# **Earthing Systems and Earth Fault Protection in Power System Distribution Network.**

A dissertation submitted by

**Sanjay Narayan**

in fulfilment of the requirements of  
**ENG4111 and 4112 Research Project**

towards the degree of  
**Bachelor of Engineering (Honours)(Power)**

Submitted October, 2019

# Abstract

Ergon Energy and Energex Limited are both subsidiary companies of Energy Queensland and have the responsibility to provide safe and affordable electricity to customers in Queensland. In maintaining a safe distribution power network, earthing and power system protection plays a vital role. This research project performs analysis on different earthing systems and various forms of earth fault protection utilised in distribution power network to improve the detection of high impedance earth faults.

Earth faults are not only by far the most frequent of all faults, but the fault currents may be limited in magnitude by the neutral earthing impedance, or by the earth contact resistance which makes detection challenging for conventional protection schemes. Currently, normal earth fault protection together with sensitive earth fault protection has been employed in both distribution networks to detect and clear earth faults. There have been incidences where earth fault detection has been extremely challenging as fault values drop significantly and the protective device does not have sensitivity to detect and isolate the faulty equipment.

In Energy Queensland's distribution power network, the neutral of supply transformers at zone substations are either solidly or impedance earth in order to provide a path for earth fault current to flow and allow subsequent operation of protective device. As part of this research project, analysis was carried out on the different forms of earthing systems currently utilised and its implications on earth fault protection. Earth faults were simulated on 11kV feeder model in DigSilent Power Factory Software package. Test cases were developed for earth fault scenarios and the results for each of the different simulated scenarios were recorded and have been discussed in results discussion.

This research project led to the identification of alternate earthing systems and improved earth fault detection capabilities in protective devices. Rapid Earth Fault Current Limiters as an alternate form of earthing / earth fault protection has been identified as part of this research study which may be utilised in Energy Queensland's distribution power network to enhance earth fault detection capabilities. Rapid Earth Fault Current Limiters performance in-terms of detection of current and speed of operation in comparison to existing traditional earth fault protection schemes and protection relay. Further work is required however in carrying out a detail feasibility study in the application of Rapid Earth Fault Current Limiters in energy Queensland's network.

## Certification of Dissertation

I certify that the ideas, designs and experimental work, results, analyses and conclusions set out in this dissertation are entirely my own effort, except where otherwise indicated and acknowledged.

I further certify that the work is original and has not been previously submitted for assessment in any other course or institution, except where specifically stated.

Sanjay Narayan

# Acknowledgments

I would like to acknowledge the assistance of colleagues at Energex, Ergon Energy and Energy Queensland, who provided support towards the research project. In particular Robert W. Coggan, EQL's Manager Protection & Earthing for providing invaluable assistance in successful completion of this research project.

I have been very fortunate to have Dr Andrew Hewitt and Mr Matthew Quinton as my supervisors during the conduct of this research project, and would like to thank them enormously for their support and guidance.

Most significantly, I would like to thank my wife Sangeeta, our son Shivan and daughter Shreya for making the all family sacrifices and completion of this research project possible, and for their endless love and support.

Sanjay Narayan

# Chapter 1 Introduction

## 1.1 Chapter Overview

This chapter outlines the motivation to undertake the research project, project initiation, project aims and the structure of the dissertation.

## 1.2 Introduction

Energy Queensland is the largest electricity distributor in Australia and has the responsibility to provide safe and affordable electricity to customers in Queensland. Its two subsidiary companies, Ergon Energy and Energex Limited have the responsibility of maintaining and building a safe and reliable power network so that communities can enjoy the benefits of having electricity to their premises. There are many challenges faced by these two subsidiary companies and one of the issues that are common to both is to be able to have a safe distribution power network. In maintaining a safe network, power system protection plays a very vital role in being able to meet the stipulated standards.

Ergon Energy and Energex Limited operate power system distribution networks which are built on different topographic layout and as such have their own challenges in providing adequate protection for the network. As topology differs, the behaviour of the network to different soil and environmental conditions during a system fault scenario differs. Earth faults are the most frequent type of all faults. The fault current for earth fault may be limited in magnitude by the neutral earthing impedance, as well as the fault resistance which makes detection challenging for conventional protection schemes. Traditionally, IDMT earth fault protection together with Sensitive Earth Fault protection has been employed in both distribution networks to detect and clear earth faults. Sensitive Earth Fault Protection was introduced primarily to clear high impedance earth faults with typical setting in the range 3amps, 3second to 8amps, 8second. Even with low pickup values there have been cases where the earth fault current was not able to be detected or the fault did not stay long enough to initiate a trip to the protective device.

A common fault scenario that occurs in both networks is a phase to ground fault. The fault current varies significantly depending on the impedance of the fault path and if the fault is not detected and cleared than it can pose a safety risk to the public. Electrical faults occur within the distribution network due to deterioration of assets, wild life, severe weather events and traffic accidents.

In Energy Queensland's distribution networks, the system neutral is earthed in order to provide a path for earth fault currents, this enables the detection of the fault and the subsequent operation of protective device. The neutral point of transformers at the zone substations are earthed by direct connection to the earth grid or connected through a current-limiting device such as a neutral earthing resistor or neutral earthing reactor. When a star-connected winding is not available (as with a delta-connected transformer winding), the neutral point is obtained by connecting an earthing transformer. In all substations there is an earth grid, consisting of a number of earth electrodes connected together by a copper earth bus, to which all transformer neutrals are connected.

## **1.3 Motivation**

### **1.3.1 Project Initiation**

Earth faults are the most frequent occurring faults in a distribution network and in some cases are not able to be detected with traditional protection types. This may occur in instances where the earth fault current is not high enough to operate the Sensitive Earth Fault Protection. It has always been a focus area to ensure that the network is adequately protected against all types of faults with earth faults seen as the most critical. There have been incidences where earth fault detection has not been possible and this poses safety risks to workers, the general public, plant and property. This research study focuses on reviewing the availability of technologies which can be utilised in the distribution power network to improve the detection of earth faults and exploring opportunities to improve safety in the distribution network.

With safety being key focus of Energy Queensland, continuing to investigate the feasibility of new technologies that support improvements in safety aligns to the organisations values. In addition to a corporate safety focus, Energy Queensland has legal obligations in designing, building, maintaining and operating the power system – this project supports these obligations. The project will provide an opportunity to explore other techniques that are effective and potentially used by other utilities. This research study will provide further insights into the improvements that can be made in the network in order to have a safe and reliable power system.

### **1.3.2 Project Aims**

Presently, there are four main types of neutral earth connection of zone substation transformer star-point or delta connected winding being utilised in the Energex and Ergon distribution networks. These are:

- Solidly grounded system
- Resistance grounding (Neutral Earthing Resistor)
- Reactive grounding (Neutral Earthing Reactors)
- Earthing transformers

The aim of this project is to investigate the effects of different earthing systems on the operation and effectiveness of earth fault protection schemes, with a focus on the Energy Queensland's distribution network.

The primary objectives of this research project were to:

- Investigate the different earthing system's used in Energy Queensland's distribution network.
- Investigate the benefits and challenges of existing and alternate earthing systems.
- Investigate the various forms of earth fault protection currently used by distribution network service providers within Australia.
- Develop suitable distribution network models for the analysis of different earthing systems.
- Research and investigate alternate protection functions currently available in protective devices from suppliers / manufactures which can be utilised for detecting earth faults.
- Research and investigate the availability of new technologies that may provide better earth fault detection capabilities.

During the execution of this research project, analysis was carried out on the different forms of earthing systems currently being utilised and its implications on earth fault protection. This study will form a vital part of research in an area which has its own challenges in meeting the various standards and industry practices to be able to provide a reliable and safe power network. It will provide an ideal opportunity to explore alternate forms of earthing systems and also other forms of protection which can assist in earth fault detection.

The successful completion of this research was important as it will result in:

- Exploring opportunities to improve safety in the network during an event of earth fault situation arising from broken conductor coming into contact with plant or property, human error leading into contact with power lines or other related causes.
- Possible solutions in detection of low values of earth fault current.
- Identification of alternate earthing systems and improved earth fault detection capabilities in protective devices.

It is important for any organisation to have safety as the number one priority as it helps to reduce hazards and accidents. If someone does get hurt, an employee, contractor or member of the public, there is human, reputational, legal and financial impact on those close to the incident and the organisation.

If time and resources permit, further research detailed in the Project Specification in Appendix A will be undertaken.

# Chapter 2 Background

## 2.1 Chapter Overview

This chapter highlights the functions of protection and earthing. It provides an overview of Energy Queensland's distribution network, distribution feeder protection and earthing system currently utilised in the distribution network.

## 2.2 Functions of Protection

Protection relays form an integral component of the power system network as they perform functions critical to the safe and reliable operation of the network. Some of these functions are:

- Detect faults and hazardous abnormalities in order to isolate the faulty section of the network within an acceptable time.
- Minimise danger to life and property.
- Reduce the extent of damage to network assets.
- Minimise the effect that a fault or abnormality has on the remainder of the network.
- Minimise the extent and duration of plant, equipment and circuit outages.
- Be reliable and secure to avoid mal-operation.

The protection systems installed are also required to comply with and perform to the requirements of:

- National Electricity Rules
- Electrical Safety Regulations
- Good engineering practice and industry guidelines
- Connection contract obligations
- Codes of practice for Earth Potential Rise (EPR) and Low Frequency Induction (LFI)

During a system fault, there can be thousands of amps of fault current generated causing significant risk to the power system network. There are also instances where fault currents are very low and thus it is difficult for protective devices to detect and clear these faults. Regardless of how well the network is designed, faults will always occur on a power system and these faults may pose a risk to life and/or property. The provision of adequate protection to detect and disconnect elements of the power system in the event of fault is therefore an integral part of power system design.

Faults on the distribution network are typically considered as symmetrical and unsymmetrical faults. Symmetrical faults are severe balanced faults and occur less frequently in the power network. The two main types of symmetrical faults are, line to line to line to ground (L-L-L-G) and line to line to line (L-L-L). Unsymmetrical faults are very common and occur more frequently in the distribution power network. The three main types of unsymmetrical faults are, line to ground (L-G), line to line (L-L) and double line to ground (LL-G) faults. Line to ground fault is the most common fault and causes unbalance in the power system. Hence protection must be designed as such that it is able to protect the power system in all different fault conditions.

## 2.3 Functions of Earthing

The electrical earthing system is designed to provide safe and correct operation of the network under normal, earth fault and transient conditions. It is fundamentally required to provide safety to people, protect plant and equipment and support operational security. During earth fault conditions, large earth fault currents may flow via the general mass of earth en-route to the neutral point of the source transformer. The earthing system, its components and earthing conductors shall be capable of conducting the expected fault current or portion of the fault current which may be applicable and without exceeding material or equipment limitations for thermal and mechanical stresses.

Earthing systems are required to manage the transfer of fault energy in such a manner as to limit the risk to people, equipment and system operation to acceptable levels. An earthing system is required to perform this function for the life of the electrical network for which it is installed, for the range of configurations of the network and nearby infrastructure that are foreseeable. The earthing system is required to manage any hazardous potential differences to which personnel or members of the public may be exposed. It is required to ensure proper operation of protective devices such as protection relays and surge arresters to maintain system reliability. Elimination of all hazards associated with earthing systems is rarely possible.

During a fault involving earth, Earth Potential Rise (EPR) may exist on earthed assets, in these cases voltages in the form of touch, step and transfer potentials may be present on and around the installation. These voltages are defined as follows:

- **Touch potential:** the difference between EPR of an earthing system and the ground surface potential at a distance of 1.0m. This is the difference between a person's hand touching an energised object and their feet which is typically assumed to be 1.0m out from the energised object.
- **Step potential:** the difference in ground surface potential between a person's feet spaced 1m apart.
- **Transfer potential:** the potential difference that may exist between the local earthing system and a metallic object (e.g. fences, pipes) bonded to a distant location that may be at a different potential.

The level of hazard present at a site during a fault or transient condition is site specific and determined by factors including but not limited to soil conditions, protection clearing times, fault current and current path. Under fault condition, the flow of current to earth will result in gradients within the path of fault current.

## 2.4 Energy Queensland's Energex distribution network overview

Energex provides power to homes and businesses in South East Queensland (SEQ) region. Its distribution network contains a mixture of short and long radial distribution feeders that are susceptible to network faults due to adverse weather conditions as well as due to normal failure of equipment or human intervention. The network also consists of parallel and ring connected feeders. Energex's distribution network operates at a nominal phase to phase voltage of 11kV AC, and phase to neutral voltage of 6.35kV AC.

The 11kV network is supplied by:

- 33/11kV Dyn11 zone substation transformers, with a secondary neutral connected to ground either directly, via a 3ohm Neutral Earthing Resistor (NER), or via 3ohm/6ohm Neutral Earthing Reactor (NEX).
- 110kV/11kV YNd11 distribution supply transformers, with a secondary connection to earth via a 9ohm earthing transformer.
- 132kV/11kV YNd11 distribution supply transformers, with a secondary connection to earth via a 9ohm earthing transformer.

## **2.5 Energy Queensland's Ergon Energy distribution network overview**

Ergon Energy has the responsibility of providing electricity to homes and businesses in the North Queensland (NQ) and Western region. Its distribution network consists of long radial distribution feeders which are built through dense bushland, farming properties or dry and sandy soil conditions. Around 70% of the electricity network exists in rural Queensland, a vast service area with long distances between communities. This part of the network have a proportionately high investment in sub-transmission assets, compared to the Energex's network and also one of the largest Single Wire Earth Return (SWER) networks in the world. In this research project, earth faults in SWER network are not considered. In comparison to Energex's meshed or interconnected network, the radial design of the rural network and the limited capacity of the SWER lines limit options when responding to peak demands and outages.

Ergon Energy's distribution network operates with a nominal phase to phase voltage in the range 3.3kV and 22kV AC, predominately the distribution voltage are 11 and 22kV. Ergon Energy also has around 64,000 kilometres of SWER distribution network which operates at 11kV, 12.7kV and 19.1kV voltage levels.

The 11kV and 22kV network is supplied by:

- 33/11kV Dyn11 zone substation transformers, with a secondary neutral solidly connected to ground.
- 110kV/11kV and 132kV/22kV Dyn11 distribution supply transformers, with a solidly neutral connection to earth on the secondary side.
- 66/11kV and 66/22kV Dyn11 zone substation transformers, with a secondary neutral solidly connected to ground.

## **2.6 Distribution feeder protection overview**

In both the Energex and Ergon distribution network, identical feeder protection schemes have been utilised. Distribution feeders are typically protected using non-unit protection schemes based on a combination of two or three phase Overcurrent (2OC/3OC), Earth fault (EF) and Sensitive Earth Fault (SEF) protection. Inverse Definite Minimum Time (IDMT) and Definite Time (DT) elements are typically employed to obtain speed and ensure discrimination is achieved, thus limiting the thermal damage sustained by the network apparatus and reducing conductor clashing during the fault. The interruption of fault current is typically achieved by a Circuit Breaker (CB) or Automatic Circuit Recloser (ACR) located within the source substation, or a pole mounted ACR located along the feeder or fuses.

Primary and back-up protection schemes are installed to ensure that if primary protection fails to isolate a fault, it will be isolated by the back-up protection. Co-ordination is achieved between protective devices either by current or time or a combination of both. This is done to ensure that relay nearest to fault operates first to minimise system disruption due to the fault. In-order to prevent incorrect protection operation, a grading margin of 300msec to 400msec is maintained between protective devices on that feeder. The protective device closest to the fault provides primary protection and operates first for that fault and the device further upstream to his device provides back up protection in situations should the primary protective device fails whilst in service.

SEF protection is designed to provide detection of high impedance earth faults on distribution overhead feeders. These high impedance earth faults which cannot be detected by normal earth fault protection, typically involve, but are not limited to, wire/s down load side with a high contact resistance to earth. In the distribution network, SEF is typically set to a minimum of 3 amps for 3 seconds to a maximum of 8 amps for 8 seconds. Neutral Sensitive Earth Fault (NSEF) protection is also implemented in substations which provides back up protection for SEF.

Figure 1 depicts a traditional network setup with the implementation of earth fault and SEF protection currently being utilised in distribution network.

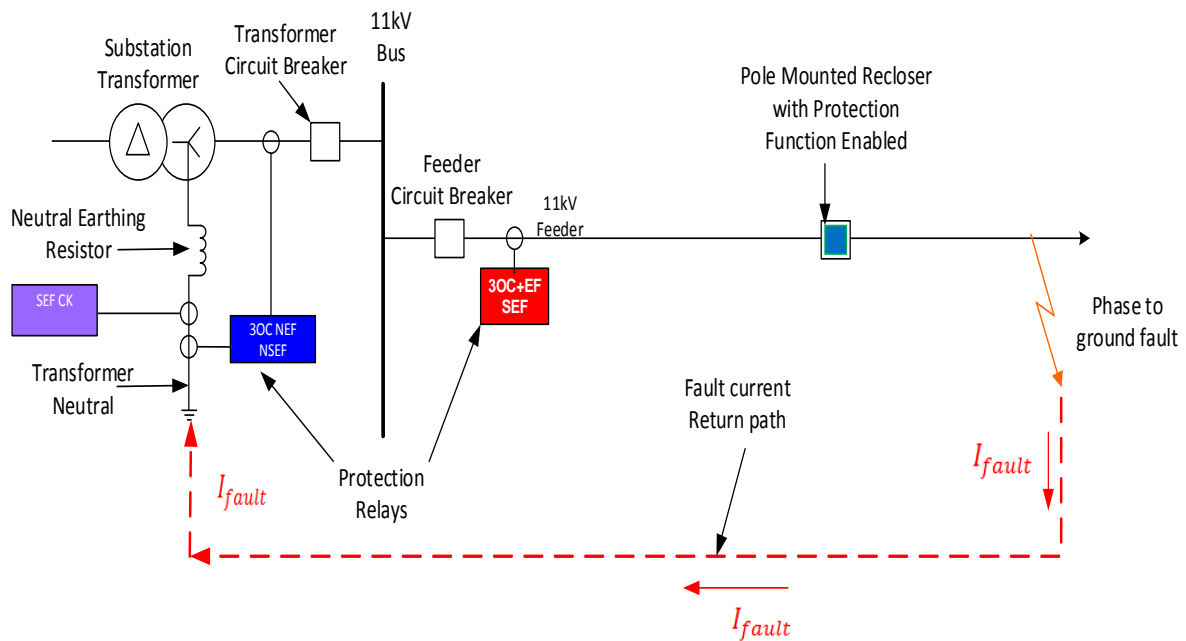

Figure 1: Typical Earth Fault protection implementation

## 2.7 Earthing System employed in Energy Queensland's distribution networks

There are a number of different methods of earthing that have been utilised in Energy Queensland's power system network. The substation earth grid is constructed as a mesh of copper conductors buried under ground the substation. Power transformers at the substation have the neutral point connected to the substation earth grid via various methods, as discussed further below in this section. Having an earth connection of the power transformers allows the fault current to return to these power

transformers. Traditionally, and as the distribution network of Energy Queensland has evolved over the years, the following earthing systems have been installed:

- **Solidly grounded system** - Only a limited number of zone substations in the Energex region have the neutral point of the star connected winding on 11kV side of the power transformer that are solidly grounded as shown in figure 2 below. As the distribution network as developed over the years in Energex region it has adopted a resistance/reactance grounding method. It is mainly due to step and touch potential issues created by large earth fault currents therefore, earth fault currents has always been limited in Energex distribution power networks. This is not the case in the North Queensland distribution region where majority network utilises a solidly grounded system. Earth fault currents are not limited in these distribution networks largely due to very long distribution feeders and network topology that earth fault currents drop quite significantly towards the remote portions of the feeders and it becomes difficult for protective devices to detect these faults. Earth fault current at the zone substation is normally in excess of 2000A – 5000A.

*Figure 2: Solidly grounded earth system*

- **Neutral earthing resistor (NER)** – a number of zone substations in Energex’s network have NER installed in the neutral point of the supply transformer. NERs limit fault currents to a value that does not cause major damage to switchgear or transformers beyond what has already been caused by the fault itself. It also provides safety to general public and personnel working in substations and other electrical infrastructure as there is control of the minimum and maximum magnitudes of phase to earth fault currents. If there are multiple transformers operating in parallel at a particular substation, all will share the same NER. All the neutral points of the transformers will be running to the NER cubicle and then a common grounding point via the NER as shown in figure 3 below. The size of this resistor is 3ohms and limits the fault current to around 2000Amps that would flow through the neutral of a transformer in the event of a close in earth fault. However the earth fault current value will decrease as the fault moves away from the source as the impedance of the conductors and ground return path comes into effect.

Using  $V = IR$  with a phase to ground voltage of 6350V (11000V/1.732)

$$I = \frac{6350V}{3\Omega}$$

$$I = 2117A$$

The fault value of 2117A is for a fault with an infinite 11kV bus.

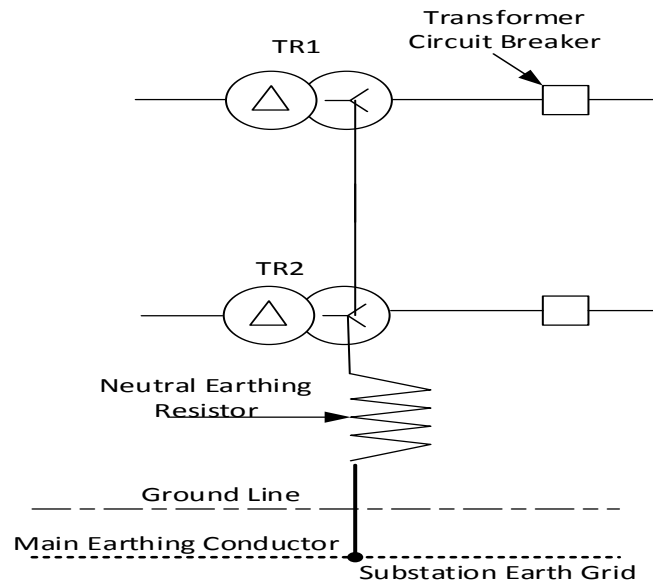

Figure 3: Neutral earthing resistor in two transformer application

Figure 4: Neutral earthing resistor in field

- **Neutral earthing reactors (NEX's)** – these have been installed only in Energex's network and more as a replacement for NER's. When new distribution substations are built or when NER's reach end of life, NEX's have been installed mainly due to ongoing maintenance cost associated with NER's. NER's are larger in size and involves larger installation area as compared to NEX's. The principle of operation is quite similar to NER's except NEX's are basically a large wound coil as shown in figure 5 below and set to 6 ohms and each transformer will have its own NEX as shown in figure 6.

Figure 5: Neutral earthing reactor connection

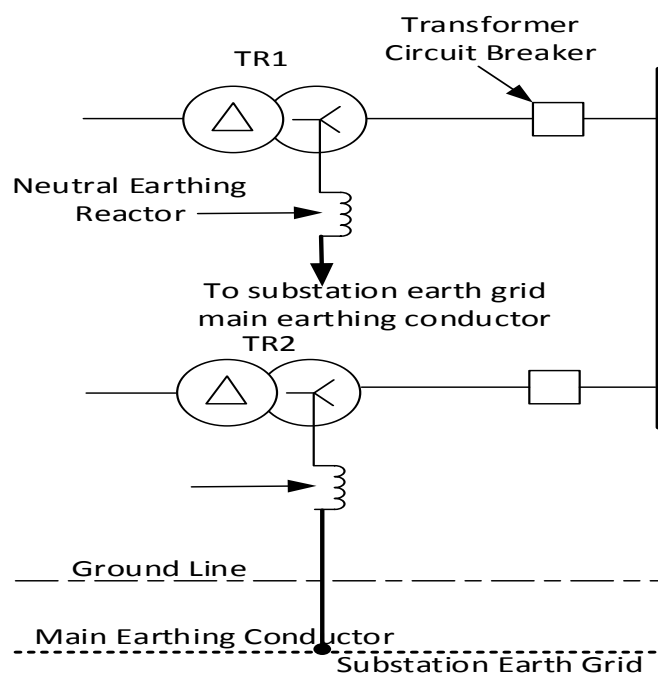

Figure 6: Neutral earthing reactors in two transformer application

*Figure 7: NEX in field*

- **Earthing transformers** – are only used in bulk substations where the secondary winding is delta connected as shown in figure 8. An earthing transformer is a three phase transformer connected to the power system to provide a neutral connection for earthing via impedance. They are intended to be inoperative during balanced voltage conditions, carrying significant current only during earth faults as it provides a low impedance path for zero sequence current whilst remains high impedance for positive and negative sequence currents. The main purpose of earthing transformer is to provide an earth reference for an otherwise unearthed part of a power system (i.e. a part supplied from a delta winding of a power transformer), and so restricts the voltage rise on the un-faulted, phase or phases during a fault involving earth.

*Figure 8: Earthing transformer application*

Earthing transformers are constructed with “zig-zag” connected windings, as shown in figure 9. Under normal, balanced system conditions, an earthing transformer draws only a small magnetising current, much the same as an unloaded power transformer. When a phase to earth fault occurs, however, the residual voltage produced by the fault causes significant current to flow into the fault and back through the earthing transformer windings as shown in figure 9.

Figure 9: Current flow during a single phase fault on a system with an earthing transformer

During a single phase earth fault at the earthing transformer terminals, the maximum fault current is calculated by:

$$I_{fault} = 3 \times I_{\phi_{et}} = \frac{3 \times V_{\phi}}{Z_{\phi_{et}}}$$

$$I_{fault} = 3 \times \frac{11000}{\sqrt{3}} \times \frac{1}{9\Omega} = 2117Amps$$

The fault value of 2117A is for an earth fault at the earthing transformer terminals.

# Chapter 3 Literature Review

## 3.1 Chapter Overview

An extensive literature review was undertaken in this chapter to confirm that the research project would fulfil a genuine capability gap, to assist in identifying alternate forms of earthing and improved earth fault detection capabilities for low values of earth fault current.

## 3.2 Different earthing systems

Shipp & Angelini (1988) highlight the characteristics of different power system grounding techniques being applied and misapplied within the electrical industry. During the early days of electrical industry only two methods of earthing systems were considered: solidly grounded systems and ungrounded systems. One of the real hazards with an ungrounded system is the occurrence of a second ground fault. Although nothing happens after a single ground fault, the second ground fault acts like a phase to phase fault. Therefore it is important to remove ground faults from ungrounded systems as soon as possible. A comparison of all voltages and currents of solidly grounded versus ungrounded systems supports that in a solidly grounded system, a very high ground fault current is available, but with low or suppressed system voltages. In an ungrounded system, the available ground fault current is very low but the voltage on the normal line to ground insulation is increased from a line to ground value to a full line to line magnitude.

Ungrounded systems are not a preferred method as line to ground faults are not cleared from the system and multiple ground faults can and do occur on ungrounded systems. The occurrence of a second ground fault on another phase will lead to line to line voltage impressed on their line to ground voltage. The phase to ground insulation is overstressed by 73% and this leads to an accelerated degradation of the insulation system, due to the collective over-voltages impinged upon it, through successive ground faults over a period of several years. Industry practices have mainly utilised solidly, resistance and impedance grounding methods over the years.

Many people are of the opinion that an ungrounded system is safer. This opinion says that since contact with a single phase does not complete a circuit, you will not get shocked. This is not the case in the real world where there is always capacitive coupling to ground. Personnel safety and the possibility of fire are not significantly different between an ungrounded system and a high resistance grounded system under solid ground fault conditions. Another area of consideration is continuity of service. A high resistance grounded system limits the ground fault current to a value only slightly higher than an ungrounded system. These values are small enough that it is acceptable to not trip safety devices and let faults remain on the system. The advantages of high resistance grounded systems are the easier location of the fault and the elimination of transient over-voltages which can lead to premature insulation failure.

Levine( 2010) discusses in great detail the advantages and disadvantages of different types of neutral grounding systems. It does a comparison on ungrounded, solidly, reactive, low resistance and high resistance grounded system's as highlighted in tables 1 to 3.

<b><i>Ungrounded Earthing System</i></b>	
<b><i>Advantages</i></b>	<b><i>Disadvantages</i></b>
<ul style="list-style-type: none"> <li>• Low value of current flow for phase to ground fault</li> <li>• No flash hazard to personnel for accidental line to ground fault</li> <li>• Continued supply on the occurrence of first line to ground fault</li> <li>• Probability of line to ground arcing fault escalating to phase – phase or three phase fault is very small</li> </ul>	<ul style="list-style-type: none"> <li>• Difficult to locate phase to ground fault</li> <li>• Does not control transient over-voltages</li> <li>• Cost of system maintenance is higher due to labour of locating ground faults</li> <li>• A second ground fault on another phase will result in a phase – phase short circuit</li> </ul>

*Table 1: Advantages and Disadvantages of Ungrounded Earthing System*

<b><i>Solidly Grounded Earthing System</i></b>	
<b><i>Advantages</i></b>	<b><i>Disadvantages</i></b>
<ul style="list-style-type: none"> <li>• Controls transient over voltage between the neutral and ground</li> <li>• Not difficult to locate the fault</li> <li>• Can be used to supply line-neutral loads</li> </ul>	<ul style="list-style-type: none"> <li>• Severe flash hazard</li> <li>• High values of fault current</li> <li>• Single-phase fault escalation into 3-phase fault is likely</li> <li>• Main breaker may be required</li> <li>• Loss of supply</li> <li>• Equipment damage</li> </ul>

*Table 2: Advantages and Disadvantages of Solidly Grounded Earthing System*

<b><i>Resistance and Reactive Grounded Earthing System</i></b>	
<b><i>Advantages</i></b>	<b><i>Disadvantages</i></b>
<ul style="list-style-type: none"> <li>• Low values of fault current</li> <li>• No flash hazard</li> <li>• Controls transient over voltage</li> <li>• Less likelihood of equipment damage</li> <li>• Safer for personnel</li> </ul>	<ul style="list-style-type: none"> <li>• (Levine, 2010) does not highlight any known disadvantages so this can be evaluated further as part of this research project.</li> </ul>

*Table 3: Advantages and Disadvantages of Resistance and Reactive Grounded Earthing System*

Shipp & Angelini (1988) and Levine (2010) both highlight that solidly, resistance or reactive grounding techniques are a more preferred method than an ungrounded system. This research project can further critically evaluate the various earthing systems in power system distribution network.

The risk of serious and fatal arc blast injuries is potentially reduced by the use of high resistance grounding Nelson (2015). Nelson (2015) suggests that an arcing ground fault on a solidly grounded system will typically propagate into a three-phase fault in the sub-cycle range, whereas a ground fault on a high resistance grounding system will not. During a series of test conducted as part of this study, it was noted that a phase to phase fault quickly propagated into a three-phase fault within  $\frac{1}{4}$  of a cycle and that the speed of propagation was so fast that there was no significant decrease with the incident energy. A similar characteristic was noted for a phase to ground fault during the testing however a single phase to ground fault will not propagate into an arcing multiphase fault and that the incident energy at the point of the fault is zero. From the study it can be seen that high resistance grounding technique plays a vital role in reducing arc blast incidences. However it does not totally improve electrical safety for contact or touch dangers, which are still the predominant cause of serious injuries and death.

Burgess & Ahfok (2011) proposed a new method of minimising the transient over-voltages in the power system network by using arc suppression coils. It suggests that arc suppression coil systems are able to improve the high voltage system reliability and safety. It is based on the Petersen coil principle whereby the coil performs the arc suppression by compensating the post-fault steady state current. The high voltage system supply point neutrals are earthed through inductors which are tuned to the total line to earth capacitance of the system. When an earth fault occurs there is very little voltage on the faulted phase and the voltages on the other phases and the neutral are displaced accordingly. This results in the normal line to line voltage being applied between the two healthy phase lines and earth for the duration of the fault. If the inductor is properly tuned, the capacitive current resulting from the voltage displacement is equal and opposite to the current in the earthing inductor. The residual current fault current will be very small and will not be sufficient to maintain the arc. Therefore there is no arc damage at the point of the fault and many faults self-extinguish.

One of the authors had personal experience of an arc suppression coil system, hence the increased risk of simultaneous faults when arc suppression coil system is being used in the system was highlighted. It was reported that due to the incident of cross-country faults, arc suppression coil was taken out of service from a transmission network. Due to these known incidences, electricity supply authorities have been reluctant to install arc suppression coil systems in Australia.

Dahal, et al.(2017) presents the impact of frequency of lightning strikes on ground potential gradients across substations. The substation earth grid and the lightning strike were modelled in CDEGS tool. The various frequencies of strikes were applied from various locations within the substations. The voltage gradients resulting from the strikes at various frequencies were observed. The results showed that when the insulator flashover occurs near a substation earthing system due to lightning strikes, a high amount of fault current is dispersed to the ground through the substation earth electrodes. Such influx of high impulse current generates significant gradients of voltage across the substation grounding system. Such voltage gradients could be dangerous to personnel and equipment within the substation. This analysis shows that the distribution of voltage gradients under impulse current is dependent on the frequency of impulse voltage. The lower the frequency of strike voltage, the lower number of voltage gradients are present across the substation. The higher the frequency of impulse voltage, a higher number of voltage gradients are present in the substation.

### 3.3 Ground fault neutralizer (GFN)

A GFN is a type of Rapid Earth Fault Current Limiter (REFCL) and is an adaptation to traditional Petersen Coil / Arc Suppression Coil (ASC) systems where a tuned reactance is placed in the zone substation neutral. A REFCL is a network protection device, normally installed in a zone substation that significantly reduces the arc fault energy generated during a phase to ground fault. The reduction in an arc fault energy can be so effective that earth fault fire ignition on 22kV three phase networks is almost eliminated.

The use of this technology is on the increase as it has been used by a number of countries globally. It is being rolled out in Victoria, Australia, after the February 2009 bushfires whereby it was found by the bushfire taskforce that many of the fires were actually started by power lines with existing protection far too insensitive to detect line to ground faults. The task force identified Rapid Earth Fault Current Limiters (REFCLs) as a new technology used primarily for supply reliability outside of Australia. They are being installed in Victoria as a world-first use of this technology to lower the risk of powerline faults starting bushfires. Testing of REFCLs at two zone substations, demonstrated REFCLs potential to prevent the most common kinds of faults on 22kV powerlines from starting bushfires. The test results assisted the Victorian Government and electrical distribution business to develop a sequence introduction of REFCLs onto the Victorian network through amendments to the Electrical Safety (Bushfire Mitigation) Regulations 2013.

#### 3.3.1 Operation of REFCLs

A REFCL operates on polyphase (3-wire) high voltage powerlines. REFCLs can detect single phase to earth faults and once the fault is detected it reduces the voltage on the faulted phase to a very low level within 2 seconds or less. REFCLs allow the electricity distribution system to continue operating for a short time rather than switching power off altogether when a fault is detected. If the fault persists, the REFCL then shuts down the power to the affected lines. But this aspect of a REFCL's operation also means that the two, non-faulted wires receive significantly more voltage than normal during these brief over-voltage conditions. Such over-voltages can have a negative effect on a high voltage customer's electrical equipment and installations if not properly assessed and modified where necessary.

Winter (Dec 2006) highlights that the GFN was initially developed for safe post-fault protection in resonance grounded overhead networks, but now also have the option of pre-fault detection. GFN has been developed by a company called Swedish Neutral, which has capabilities to detect earth faults with response times of less than 60ms. Instead of tripping the faulty feeder, the GFN cancels out the fault current by injection of an anti-phase current into the neutral and brings the fault current down to practically zero making it possible to maintain safe operation without disturbing power supply to customers. It is connected to the neutral of the supplying power transformer (Y – winding) as shown in figure 12 or a separate grounding transformer (Z-winding). A complete GFN system is composed of a modern solid core arc suppression coil (ASC), a cabinet with power electronics for voltage/current injection (RCC – Residual Current Compensator) and the GFN control cabinet as shown in figures 10 and 11 below.

Winter & Winter (2019) mentions that beside the controls for the RCC voltage / current injection, the GFN also provides automatic returning for the arc suppression coil and a new twin-scheme fault locator with superior detection capabilities. The arc suppression coil forms a parallel resonant circuit with the phase to ground capacitive leakage of the network. By this resonant circuit the source

impedance for single phase to ground faults increases in the order of ten to twenty times, sufficient to quench single phase flashover faults on overhead lines.

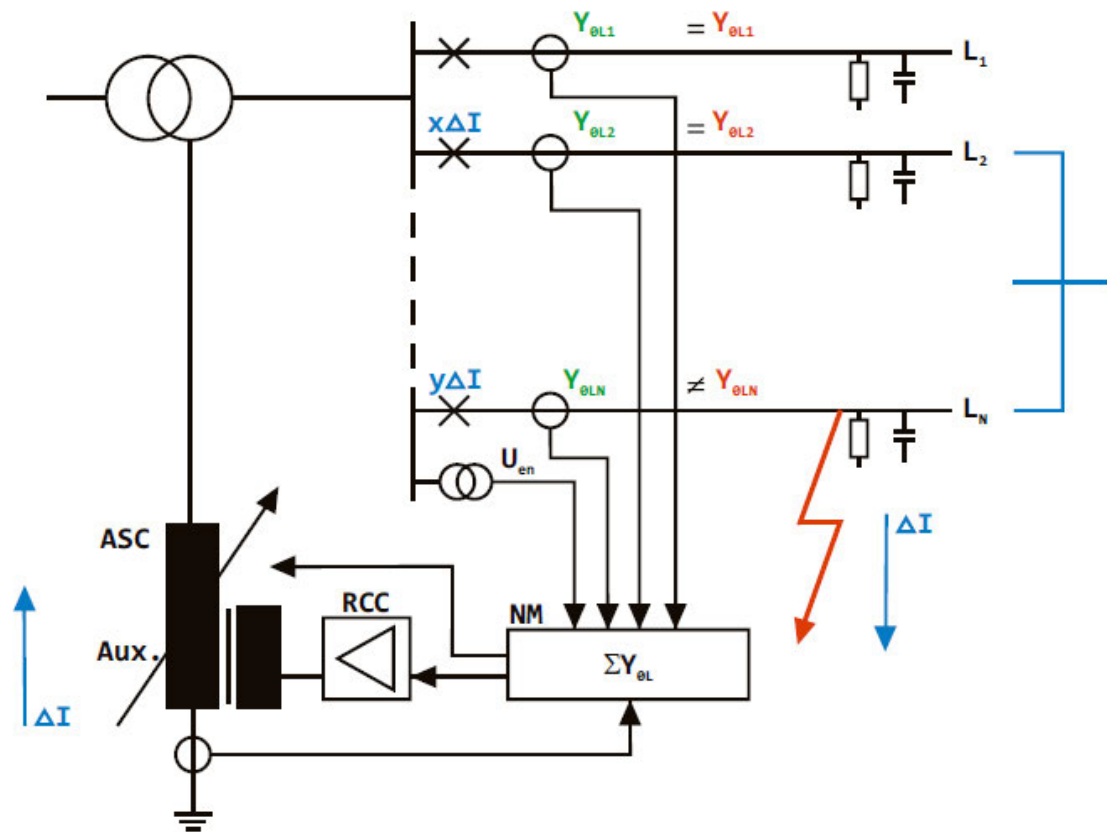

*Figure 10: Control Cubicles and Transformer*

*Figure 11: Arc Suppression Coils*

*Figure 12: Typical Ground Fault Neutraliser setup*

This technology does possess features which have been further investigated as part of this research project. It does have capabilities which can be utilised in resolving the issue of earth fault detecting to both Energex and Ergon Energy's distribution network. Whilst the use of REFCL's has been rolled out and also currently being installed in Victorian distribution power networks, the suitability of the device in EQ's distribution network has been investigated as part of this research project. Analysis on existing HV components of the network to see if it can withstand full system voltage displacement will need to be carried out.

### 3.3.2 Victorian Government Legislation

Marxsen(2014) highlights that after the 2009 bushfires in Victoria, the Victorian Bushfire Royal Commission initiated the Powerline Bushfire Safety Taskforce (PBST) in 2011. The PBST's primary purpose was to investigate different options to reduce the harm to people and property from bushfires started by electrical assets. The PBST identified REFCLs installed in zone substations as an efficient and effective technology.

The Electricity Safety (Bushfire Mitigation) Amendment Regulations 2016 which came into operation on 1 May 2016 set out new requirements for major electricity companies including the requirements for major electricity companies including the requirement for Polyphase Electric Lines (defined as

multiphase distribution between 1kV and 22kV at selected zone substations to have the following abilities:

- To reduce the voltage on the faulted conductor for high impedance faults to 250 volts within 2 seconds.
- To reduce the voltage on the faulted conductor for low impedance faults to;
  - 1900 volts within 85 milliseconds ; and
  - 750 volts within 500 milliseconds; and
  - 250 volts within 2 seconds; and
- Demonstrate during diagnostic tests for high impedance faults to limit;
  - Fault current to 0.5 amps or less; and
  - The thermal energy on the electric line to maximum  $I^2t$  value of 0.1

The Amended Bushfire Mitigation Regulations define the low and high impedance faults as follows:

- High impedance = a resistance value in Ohms that is twice the nominal phase to ground voltage. This is equal to 25.4kΩ or a fault current of 0.5 amps on a 22kV network.
- Low impedance = resistance value in Ohms that is the nominal phase to ground network voltage divided by 31.75. This is equal to 400 Ohms or a fault current of 31.75 Amps on a 22kV network.

### 3.3.3 Findings of REFCL Trials in Victoria

Marxsen(2014) highlights rigorous tests on a real electricity distribution network carried out in Victoria, have confirmed that Rapid Earth Fault Current Limiter (REFCL) technology can reduce the fire risk associated with bare-wire overhead powerlines. Tests confirmed that when a live high voltage conductor falls to the ground under worst case fire weather conditions such as those experienced on Black Saturday 2009, a REFCL can reduce the conductor-soil arcing in many circumstances to levels below that required to start a fire. The test program confirmed that under worst case fire conditions, ‘wire on ground’ powerline earth faults on Victorian rural power distribution networks with traditional network protection systems create an inherent risk of fires and that this risk is markedly reduced in a network protected by a REFCL.

The specific findings of the research program are:

- In worst case fire conditions, ‘wire on ground’ powerline faults on networks with traditional non-REFCL protection create an inherent risk of fire. There is a very low threshold level of current into soil above which ignition is close to 100 per cent probable in today’s non-REFCL networks.
- Existing non-REFCL Sensitive Earth Fault (SEF) protection schemes have the potential to prevent some fires. However, they cannot eliminate the majority of fire risk from ‘wire on ground’ powerline faults. Other over-current earth fault protection schemes have limited if any, potential to cut fire risk.
- REFCLs dramatically reduce energy release into the environment from ‘wire on ground’ powerline faults. They collapse the voltage on the fallen conductor to reduce fault current, reduce arc power and bring about faster arc self-extinction. Tests with and without a REFCL vividly demonstrate this dramatic reduction of arc energy.
- REFCLs can detect and respond to ‘wire on ground’ powerline faults that traditional non-REFCL network protection cannot ‘see’. For supply reliability and security purposes,

traditional SEF protection is usually set to detect nine amps of fault current in rural networks. REFCLs detect two amps and tests demonstrated detection of less than one amp.

- REFCLs can significantly reduce fire risk for a wide range of ‘wire on ground’ powerline faults. By detecting earth faults that traditional protection systems cannot ‘see’ and by dramatically reducing energy released into the local environment when earth faults occur, REFCLs reduce the chance of ignition across a wide range of earth faults.
- There are some ‘wire on ground’ powerline earth faults where today’s REFCL products may not prevent ignition. High current faults may result in bounce ignition before a REFCL has time to reduce the fault current. The reduction in residual fault current may not be sufficient to completely remove the risk of slower ground ignition.
- REFCLs offer benefits to public safety. REFCLs quickly reduce the voltage on a fallen conductor and can potentially transform high voltage electrocution risk of irreversible serious internal and external burns, to low voltage electrocution risk of reversible injury that is responsive to immediate first aid, especially CPR. A GFN has the potential to reduce voltage on a fallen conductor to levels where even low voltage electrocution risk is low.
- REFCLs offer benefits to supply reliability. Improved supply reliability is a major motivator of utilities’ adoption of REFCLs around the world.

Successful management of an earth fault incident on a GFN-protected network in high fire risk conditions requires the GFN to perform the following sequence of actions:

- a) Detect the fault.
- b) Ascertain which phase of the faulted network is carrying the fault current to earth.
- c) Compensate residual current by injecting a voltage into the network neutral connection to move the voltage of the faulted phase close to zero.
- d) After a few seconds, test to see if the fault is still present.
- e) If the fault is still present, identify the feeder on which it is located.
- f) Trip the faulted feeder to remove the fault from the network.
- g) Switch off the residual current compensation so network voltages return to normal levels.

The test program confirmed the first three of these actions:

- Fault current of just one amp was detected by the GFN, albeit with sensitivity heightened above normal levels by reducing the neutral voltage detection threshold from 30 per cent to 20 per cent. With normal sensitivity settings, the GFN detects earth faults of two amps magnitude.
- Residual current compensation reduced the soil current to zero (the voltage on the conductor dropped to 200-400 volts - insufficient to drive any current across the conductor/soil interface).

The next two tasks in the sequence (to confirm whether the fault is still present and if so, reliably identify the feeder on which it is located) pose fire risk challenges as they require some soil current to flow for the GFN to make the required measurements. The final two tasks (trip the faulted feeder, switch off the residual compensation to return the network to normal operating condition ready to deal with another fault) are relatively straightforward.

In summary, the GFN offers virtual elimination of residual fault current into the soil but then faces a challenge during confirmation of the continued presence of the fault and identification of the faulted feeder, both of which require some current to flow. The challenge is to perform these functions at a

level of current flow too low to produce a ground ignition event or to do it faster than ‘time to ignite’ at the particular current level used.

### 3.3.4 REFCL Implications

Based on the test results of the trials performed in Victoria Marxsen(2014), the following implications were highlighted:

- Fully exploit modern technology in non-REFCL protection systems - The test program demonstrated that sensitive earth fault (SEF) protection systems may have the capability to prevent some ‘wire on ground’ fire starts. This capability depends on SEF fault detection sensitivity and speed of action. Over the last few decades, SEF relays have changed from analogue devices with internal moving parts to digital devices offering very high precision and reliability in both current measurement and timing of response. Many of these new devices offer improved measurement technology such as 50Hz filters to reduce their sensitivity to network transients.
- Monitor transient faults in REFCL networks to assess relevance to fire risk - REFCL protected networks deal with transient faults by temporarily displacing network voltages to reduce the fault current to such a low level that most faults simply go away (arcs self-extinguish), whereupon the network can return to normal voltage levels. It is not clear what sort of event could start a fire while presenting to a REFCL-protected network as a transient fault. In traditional non-REFCL network protection, there are many examples of transient faults that can start fires, including conductor clashes (that emit molten metal particles) and bird/animal contacts (that result in a burning carcass falling into the dry vegetation under a pole).
- For sustained faults in REFCL networks trip the faulted feeder and do not reclose - The test program has shown that REFCLs can greatly reduce fire risk from sustained earth faults such as fallen conductors. On a Code Red day, once a REFCL fault-confirmation test has demonstrated that an earth fault is permanent, there is little option available to a network owner but to trip the faulted feeder - provided of course that it can be confidently identified. Unlike traditional non-REFCL network protection, reclosing onto a known permanent earth fault serves little purpose in a REFCL-protected network – the REFCL reduces the fault current to such an extent that downstream devices will not operate to isolate the section of the network containing the fault. Hence the rule on high fire risk days should be to ‘trip and do not reclose’ which immediately highlights the challenge of fault location. Some feeders are very long (50-100 kilometres) and physical patrol is a task not undertaken lightly.
- Temporarily increase REFCL fault detection sensitivity on high fire risk days - Every REFCL system faces the same hierarchy of decisions when a fault occurs: Is there a fault on the network? What phase is it on? Is it permanent? What feeder is it on? The challenge of answering these questions increases as the hierarchy is traversed. As a first step, it is relatively easy to detect faults with very high sensitivity. Today’s REFCL products operate to reliably detect faults that draw two amps of current from the network. This level of sensitivity is a marked improvement on traditional non-REFCL systems, but could be even further improved. The limits to fault detection sensitivity are determined by a number of factors.
- Promote continued development of the GFN fault confirmation test - Whilst it is relatively easy to detect faults with very high sensitivity, it is much harder to identify the feeder on which the fault has occurred. To do that, some accurately measurable 50Hz fault current is essential. Unambiguous identification of the faulted feeder without allowing enough current flow to start a fire is perhaps the toughest challenge facing REFCL developers. There is little

point in knowing there is a fault on the network if there is no information to identify the feeder that has to be tripped to prevent a fire.

### 3.3.5 REFCL Implementation Challenges

From Marxsen(2014), trials performed in Victoria, power system distribution network owners must address a number of implementation challenges as highlighted below:

- Learn by doing - culture change for network owners and suppliers - The change from non-REFCL to REFCL-based network design and operation is profound. Fire risk priority is a new challenge for REFCL developers. Intuition and integrated expert thinking about REFCL operation takes years to develop. Overseas utilities that have made the change to REFCL network protection report the most difficult challenge is the culture change required to get full value from the new technology. They comment that it takes four to five years for network operations staff, protection and control engineers and network planners to learn the new technology and how to apply it to the point they have successfully integrated this knowledge into their work.
- Harden networks to reduce risk of cross-country faults - When an earth fault occurs, the REFCL response creates voltage stress on network equipment connected to un-faulted phases, which can lead to a second fault. Outcomes can be worse than if a REFCL were not installed. Victoria's existing networks have many old items of network equipment that are not rated for continuous operation at 22kV; when an earth fault occurs on a REFCL-protected network, over-voltage on un-faulted phases can lead to failure of some of these items. Such equipment failure constitutes a second earth fault on the network, termed a 'cross-country fault' because it is usually remote from the initial fault and is always on one of the un-faulted phases subject to over-voltage stress caused by REFCL response. REFCLs can only deal with multiple earth faults if they are all on a single phase. With a cross-country fault, the network has a two-phase-to-earth fault and high currents will flow in both fault locations; two fire starts are possible, i.e. a worse result than if a REFCL had not been installed.
- Upgrade networks to REFCL compatible equipment - Some network equipment currently used in power system distribution network is not compatible with REFCL operation and must be upgraded or replaced with equipment that is compatible. These include open-delta voltage regulators, three-phase equipment in earthed star configuration, non-directional earth fault protection, etc. Incompatible equipment can prevent correct REFCL operation and may produce dangerous network conditions with a REFCL in service.
- Minimise network imbalance - The three phases of the network have different capacitances to ground. The REFCL will tune to the total network capacitance. Residual earth fault current will differ by faulted phase and be larger than if network capacitance was balanced. Fault detection sensitivity is also constrained. When an earth fault occurs on a resonant earthed network, the fault current falls to a low level made up of three components:
  - Resistive leakage current from the network to earth – the sum of all the tiny currents across the surfaces of tens or hundreds of thousands of insulators, plus current due to energy lost in cable insulation and in the iron core of the REFCL coil itself. A GFN uses its RCC to cancel this current, but an ASC cannot do the same.
  - Current due to mismatch in the tuning of the REFCL coil to the network. REFCL designers take pains to ensure tuning is accurate to within an amp or two.
  - Current due to imbalance in the capacitance to ground in each of the three phases of the network. This is under the control of the network owner.

Capacitive imbalance has some potential negative effects on REFCL performance:

- It increases residual current, i.e. ground fire risk.
- It increases the standing level of neutral voltage, i.e. it constrains fault detection sensitivity.

Long single phase (two-wire) spurs teed off three-phase lines can create significant capacitive imbalance. As fire risk reduction relies on low residual fault current, capacitive imbalance can pose a risk to fire safety and so must be managed.

- Fault location - REFCLs reduce fault current to such low levels a fault may not generate enough visible evidence to reveal its location. Permanent faults may not be located for long periods. When a permanent fault occurs in power system distribution networks, protection systems isolate the section of the network that contains the fault and with some exceptions in remoter areas, a line crew then patrols the isolated section of network to find and repair the fault so power can be restored. Often the evidence of the fault is obvious – a car into a pole, a tree fallen across the line, etc. The fault current itself is often sufficient to do enough damage to make the fault location plain. With a REFCL, the fault current can be as low as a few amps and many faults leave no evidence at all. This is not a problem for momentary faults, but it is a challenge in the ten to 15 per cent of faults that are permanent. In this small but very important category of faults, the network operator can face some potentially unpalatable options, such as:
  - Allow the network to remain in a condition of full neutral voltage displacement while searching for the fault using sophisticated remote sensing devices.
  - Revert to non-REFCL network protection and allow high earth fault currents to flow to expose the fault location in the usual way. The fire risk inherent in this option means it is only acceptable at times of low fire risk. This approach can lead to further challenges if the fault is not detected by traditional protection systems but only by the REFCL – a not uncommon outcome, given the REFCL's superior fault detection sensitivity.
  - Trip the whole feeder to remove power supply to the fault. If a patrol finds no obvious cause, open all switches along the length of the feeder and restore power from the substation end section-by-section until the fault appears again. This can result in lengthy customer supply outages and the whole feeder may sometimes be restored to supply without the fault re-appearing.

Most stakeholders facing this challenge look to a future where smart grid schemes gather and analyse information from devices spread across the network, identify the most likely fault location and initiate appropriate switching to isolate the relevant section of network. Such devices can be built into pre-existing equipment, such as ACRs, or they may be new FPI (Fault Passage Indicator) products with sensitive current detection and remote communication facilities.

From all the literature and test results available it can be seen that GFN does offer the most effective and latest technology that is available in the market that can address the issue of low level fault current detection. The suitability and viability of this device in Energy Queensland's distribution network will be discussed further as part of this research project.

### 3.4 Earth Fault Detection

Wang, et al.(2017) paper presents a protection scheme for faulty feeder detection based on the grey relation degree that can characterize the similarity among curves. Slope relation degree, is chosen to characterize the similarity of transient zero-sequence current waveforms between one feeder and other feeders, and the slope relation matrix that represents the relationship among all feeders can be established. When single phase-earth fault occurs in resonant grounding system, the similarity of transient zero-sequence current waveforms between faulty feeder and sound feeder is lower than that between any two sound feeders. Therefore a variety of grey relation degree, such as absolute degree and relative relation degree can be used to characterize the relationship among transient zero-sequence waveforms. This paper designs a multi-agent protection system for faulty feeder detection, including protection starting agent, current data extraction agent, calculation agent and fault analysis agent. As the detection is based on numerous equations and step by step process, this could lead to errors and probably won't work as intended during a fault scenario. The protection method proposed in this paper is applied to detect the faulty feeder for distribution networks. Besides, it is applicable to the system where at least 3 or more feeders are present, so the protection method has certain limitations. The process and method of extracting fault data and exactly how to improve the margin to detect the faulty feeder is not discussed in this paper which will require further research.

Abdel-Fattah & Lehtonen(2010) paper presents a transient probabilistic-based technique for earth fault detection in isolated and compensated neutral medium voltage networks. It utilises Bayesian theorem as a probabilistic-based selectivity function to indicate the probability of the feeder to be faulted and is given as:

$$\Pr(\text{feeder } i \text{ is the faulty}) = \frac{f_1(I_{ni})/f_o(I_{ni})}{\sum_{i=1}^n f_1(I_{ni})/f_o(I_{ni})}$$

A 21kV, 251km medium voltage distribution network was simulated by ATP/EMTP program. Extensive simulations were performed to validate and trial the technique, for different fault conditions. The analyses were calculated in a sliding window of 2.5ms. Based on the results from the simulations, it is found that the performance of the probabilistic-based selectivity function is superior; it is not affected completely by different fault conditions and can cover the problem of low fault currents such as in isolated and compensated neutral networks and high resistance conditions. Although the theory and analysis does make logical sense, there is still lot of work required in terms of manufacturers developing algorithms to incorporate this logic. This will allow relays to analyse the waveforms itself rather than deploying other devices in the network. It would be a very costly exercise without having protection relay manufacturers involved.

Gomes, et al.(June 2018) has identified the presence of high frequency content during a high impedance earth fault involving vegetation. The testing process involved using a real dataset comprising a large number of experiments, sampled in a functioning 22kV network in the presence of noise. There were three main types of test conducted using a built in test rig. The first fault type simulates a tree branch laid across two conductors, one earthed and one with the nominal phase voltage (12.7kV). The second type followed the same geometry, but with both conductors energized (22kV). The third test was conducted by dropping the high voltage conductor into vegetation, either grass or bush. The current and voltage waveforms were sampled simultaneously in two channels to ensure wideband, and low sampling noise. The study however could not conclude that this method could be used to detect a high impedance earth fault scenario. It highlighted that further work needs to

be undertaken as voltage signals and their respective high frequency content can be hard and expensive to obtain considering network topologies and existing hardware.

Theron, et al.(January 2018) emphasises how important it is to detect and isolate high impedance earth faults. The study looks into the effectiveness of existing techniques that are currently being utilised and also highlights some of the newer developments that are available. One such technique is using negative sequence current for detecting of broken conductors. The down side of using this is the risk of unnecessary tripping due to load. In a three phase system, if one phase is lost (open bridges), it will be seen as a phase-phase fault which will generate negative sequence current and depending on the load, the feeder can trip on negative sequence protection which some of the power utilities do not want to trip for that scenario. Another technique the study looks into is the use of watt metric protection which is used in Peterson coil grounded systems. It seems to be a well established form developed over the years which can be further investigated as part of my study to see if it can be used in the distribution network. It also looks into ground wire grid form of protection which is a mechanical solution. It includes laying of guard wire under the power conductor. Since it requires wire mesh along the entire length of the distribution feeder, it will be a very costly exercise considering the geographical area of the Energex and Ergon networks. The newer technique this paper highlights is fundamental analysis and harmonic analysis which are yet to be introduced and trialled by relay manufactures as it will require algorithms developed and features introduced as part of the relay software.

Ravlic, et al.(2017) specifically highlights the method of using Fourier transform and design of intelligent system to detect earth faults. The different simulation condition takes into consideration, three phase load switching, three phase line without load switching and also three phase capacitor bank switching as these events generate similar transients to a high impedance earth fault which can lead to mal-operation of protective devices. Various phase to ground faults were simulated and the amplitude plus phase of the first, third, fifth and seventh harmonics of the zero sequence line currents were extracted using Fourier transform. Whilst from the results obtained from this study suggest that this method can be utilised, it will require further research from relay manufacturers to develop relay algorithms which incorporates this logic. The other down side is it will require voltage transformers at sites where this feature will be utilised and this is not entirely possible due to cost and other hard ware installation constraints.

Wester (1998) reviews several mechanical and electrical methods of detecting high impedance faults. One type of mechanical HIF detection method consists of a device(s) mounted to a cross arm or pole. A unit is mounted under each phase wire and it provides a low impedance ground fault by catching the falling conductor. The force of the falling conductor releases an internal spring that ejects a bus bar to make contact with the fallen wire and create a ground fault. Sagging conductors that do not come in contact with earth or a grounded object could be detected by this mechanical method. Another type of mechanical HIF detection method uses a pendulum mounted aluminum rod with hooked ends. It is suspended from an under-built neutral conductor. The falling conductor is caught and produces a low impedance ground fault, which operates conventional overcurrent protection.

The electrical methods reviewed by Wester (1998) includes:

- High Impedance Fault Analysis System – this method measures the third harmonic current phase angle with respect to the fundamental voltage. The device calculates and stores the average ambient third harmonic current phasor. When a fault occurs, the new third harmonic current phasor is vectorially subtracted from the stored value. A high impedance fault is

issued if the magnitude is above setting and angle matches a predetermined value for a down conductor.

- Open Conductor Detection – this method detects loss of voltage to determine a broken conductor. The system measures the voltage at each end of a single phase lateral. When the voltage of any phase drops below the specified threshold, a transmitter sends a signal on the neutral conductor to a receiver at the upstream device which opens if voltage is present.
- Digital Feeder Monitor – is based on the high impedance fault detection technology which uses a high waveform sampling rate (32 samples/cycle) for the AC current inputs in conjunction with a high-performance microprocessor to obtain the frequency response required for arcing fault detection.

The mechanical methods suggested in Wester (1998) will be a very costly exercise to the distribution power utilities, considering each unit will have to be mounted to a pole and will only cover one span of overhead conductor. The mechanical methods are not economically viable but could potentially be installed around schools or identified problem portion of the network. The electrical units can also be utilised but have to install one unit per distribution feeder which again will lead to significant cost considering installation and maintenance costs to these devices.

Zamanan, et al.(2007) presents a new method of detecting HIF's in distribution systems using real coded genetic algorithm (RCGA) to analyse the harmonics and phase angles of the fault current signals. The method is used to discriminate HIF's by identifying specific events that happen when a HIF occurs. It looks at the arcing nature of high impedance fault current, HIF model, harmonic model, genetic algorithm and fitness function. A practical power system is simulated in Simulink to demonstrate the ability of the RCGA to track harmonics during normal and abnormal conditions in a power system. A decision whether there is a HIF is based on the existence of the 3<sup>rd</sup> and 5<sup>th</sup> harmonics and the angle shift of the 3<sup>rd</sup> harmonic with respect to the fundamental current. After many simulations, a threshold was specified for the harmonics and the angle shift to determine a HIF. For the 3<sup>rd</sup> and 5<sup>th</sup> harmonics a 1% and a 0.5% of the fundamental current were set as threshold values respectively.

From Zamanan, et al.(2007) test results it can be seen that before the HIF occurs, the load current is normal with no change in the phase angle and no harmonic currents. After the HIF has been applied there is an increase of 13.7 amps in the load current, which can be interpreted by the protection relay as a load increase instead of a fault, simply because the HIF does not draw sufficient current for the relay to act. In a normal fault, the current in the fault will be much greater than the relay setting, therefore the relay will react to the fault. In the HIF case this will not happen because the setting in the relay is much less than the HIF current. During the existence of the HIF there is a noticeable change in the circuit harmonics. The existence of the 3<sup>rd</sup> and 5<sup>th</sup> harmonics, plus the slight increase of load current and the angle shift of the third harmonics with respect to fundamental current, together confirm the existence of the HIF, since these are the peculiar characteristics of a HIF.

The identified method involves equations and algorithms that will need to be incorporated in protective devices to achieve its intended purpose. Relay manufacturers will have to develop their own algorithm which can work in conjunction with the proposed RCGA hence it will require resources and adequate funding towards it.

Wang, et al.(2018) proposes a new faulty phase selection method for single-phase grounding faults in distribution networks with full compensation arc suppression technology. The full compensation arc suppression technology in distribution networks could be divided into current arc-extinguishing methods and voltage arc-extinguishing methods. The current arc-extinguishing methods use the neutral point grounding reactance to compensate the ground fault residual current. The voltage arc-extinguishing method involves adjusting the voltage of the faulty phase whereby the arc-suppression technology is designed to guarantee the faulty phase voltage equals zero by injecting current through the neutral point.

A resonant grounded distribution network with full compensation arc suppression technology is as shown in figure 13 below.

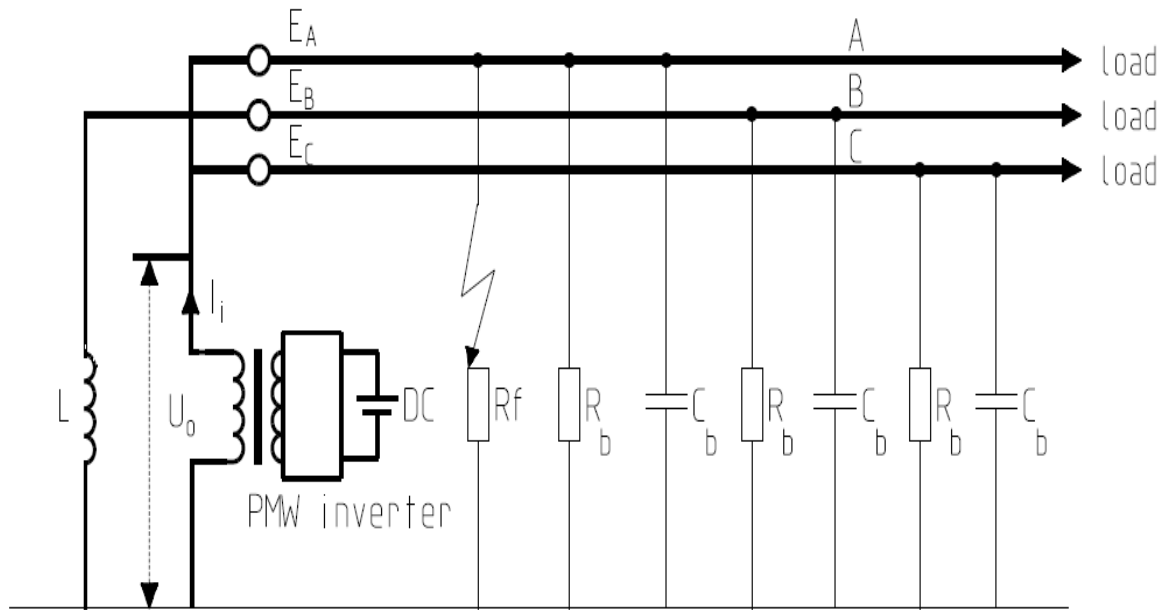

Figure 13: Resonant grounded network with full compensation arc suppression technology

$E_A$ ,  $E_B$ ,  $E_C$ , are respectively the three-phase power supply voltage in the distribution network.  $U_o$ , represents the neutral point displacement voltage after the ground fault occurs while  $L$  is the inductance of the arc-suppression coil. Compensated current  $I_i$ , is injected by the PWM active inverter. By setting a reasonable value, letting  $U_o = -E_A$ , and thus the fault phase voltage

$U_A = E_A + U_o = 0$ , that is the fault phase recovery voltage is always 0 and hence the arc can be suppressed effectively. In Wang, et al.(2018), the electromagnetic transient simulation software PSCAD is used to establish a 10kV asymmetric neutral point arc suppression coil grounding system. From the waveforms and test results obtained by the simulations it can be concluded that if the phase selection is correct, the selected phase voltage will be close to 0 when the theoretical current value determined by the zero residual current arc suppression is injected. If the phase selection is wrong, the wrongly selected non-fault phase will approach to a non-zero certain value with the increase of grounding resistance when the current is injected. The simulation analysis shows that the proposed method can correctly perform faulty phase selection which can be used to improve the full compensation arc suppression methods in distribution networks.

### 3.4.1 Voltage Supervised SEF Protection

Anegondy, et al. (2019) highlights a new approach to detecting vegetation faults by developing algorithm to improve sensitivity detecting high impedance faults using zero sequence or residual current based on high-accuracy phase current measurements supervised by zero and negative sequence voltages. Extensive system simulation studies have been performed using an Electromagnetic Transient Program (EMTP) model for a feeder in a proposed pilot project in Evoenergy distribution power network. Evoenergy operates power network in Australian Capital Territory (ACT) and faces similar issues of detecting low values of fault current. The vegetation or downed conductor fault detection algorithm has been aimed at detecting a broken or downed conductor utilising Voltage-Supervised Sensitive Earth Fault (VS-SEF) settings incorporated in pulse closing device. It has been developed to identify a broken or downed conductor situation, trip or alarm and prohibit reclosing on the circuit, thus isolating the fault and avoiding any potential ignition of a bushfire.

The algorithm was developed considering the following scenarios:

- Tree branch touching the conductor, and downed conductor on the ground, a scenario wherein a conductor snaps and lands on dry ground or grassland.
- Downed conductor, but not touching the ground, a scenario wherein a conductor snaps and hangs above the ground.

#### 3.4.1.1 Point on wave closing

Pulse-closing is a new technology and an alternative to conventional reclosing for overhead distribution system protection as highlighted in Anegondy, et al., (2019). It uses a new method to test for the continued presence of faults that reduces the energy ( $I^2t$ ) to less than 5% as compared to conventional reclosing. While the consequences of initial fault clearing cannot be avoided, subsequent fault testing using pulse-closing causes almost no decrease in the bus voltage and significantly reduces power system equipment stress, including the substation transformer through which the fault is supplied. In fact, this revolutionary fault-testing method is so un-intrusive, its operation is virtually imperceptible to all upstream loads. The reason pulse-closing is essentially transparent to upstream loads is because the very slight voltage dip caused by a fault-testing pulse lasts for a maximum of 0.5 cycles. As a result, once the initial fault is cleared, upstream loads and those on adjacent feeders are no longer affected by repeated testing for fault presence.

Pulse-closing generates a 0.25- to 0.5-cycle minor loop, or pulse, of current by rapidly closing and opening single-phase fault-interrupting contacts at specific voltage point-on-wave angles as shown in figure 14 below. A pulse is immediately analysed to determine whether it reflects fault or load current. If the predicted symmetrical current is less than the specified fault current threshold, the pulse current algorithm concludes that there is no fault and closes the per-phase contacts. Conversely, if the predicted fault current is greater than the fault current threshold, the process concludes that a fault still exists on the line and the device mechanism inhibits closure. This approach ensures that there is no heavy current closing that may result in sparks causing bushfire ignition dangers.

Figure 14: Pulse-closing concept waveform

Due to its low energy closing, transformer terminated lines are not subjected to high intensity fault closures nor overvoltage. This would benefit the transformer by extending its design life. Should the pulse-closing device trip or open three-phase (for whatever reason), and a pulse-closing operation precedes its reclosing, protection-level transformer magnetizing inrush current never occurs because pulse-closing occurs near peak voltage on each phase whereas maximum inrush current occurs when closing at a voltage zero when the voltage is increasing in the same direction as the polarity of the remnant flux trapped in the transformer core during opening. This will obviate any protection-related mal-operations due to transformers being energised under no-load conditions.

### 3.4.1.2 Voltage-Supervised Sensitive Earth Fault (VS-SEF) logic

As per Anegondy, et al., (2019), this protection scheme detects high-impedance faults by using a combination of under-voltage, neutral voltage displacement, SEF pickup, and non-operation of the normal overcurrent and earth fault protection. High-impedance faults caused by fallen conductors on ground or vegetation results in loss of voltage on one or more phases that could produce either a partial or a complete loss of voltage depending on the arc resistance. The under-voltage protection could be set to as low as 50% of nominal voltage. This unbalance results in neutral voltage displacement in the form of zero sequence voltage. Sensitivity studies have demonstrated an increase in the neutral displacement voltage and the negative sequence voltage.

In case of high resistive vegetation faults, an operation of VS-SEF at or above one ampere is used in conjunction with under-voltage, neutral voltage displacement, negative sequence and the non-operation of the normal overcurrent earth fault and SEF protection to confirm a possible vegetation fault that may result in bushfire consequences. In case of high impedance vegetation fault, the neutral current could be as low as a few amperes or less. To distinguish between a normal scenario and a faulted scenario, the system unbalance is monitored through the sequence components and the decision to trip is made when there is voltage unbalance in the network, a single phase high voltage,

and a residual zero sequence current is detected. The system unbalance setting monitors both negative and zero sequence components present in the network. Either of the components present above the threshold setting signifies an unbalance in the network, which may be because of an actual fault. Restrain values can be set for both negative and zero sequence components to allow phase overcurrent or other elements to operate instead of SEF.

The developed logic for VS-SEF is as shown in figure 15 below.

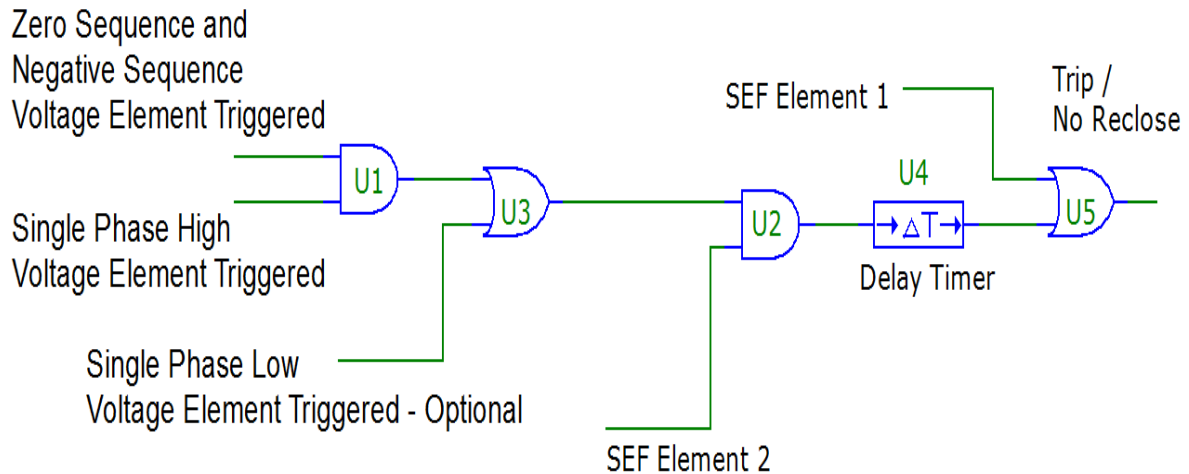

Figure 15: VS-SEF logic block diagram

Secondary injection testing has been conducted using test plans developed on an Omicron test kit. The aim of the Omicron injection testing was to prove the VS-SEF algorithm and the secondary level sensitivities of the zero sequence current and the sequence components of voltages under downed conductor or vegetation faults scenarios. The following VS-SEF tests have been conducted:

- As per the logic, the SEF combined with a single phase low voltage will initiate the trip after the delay timers – definite time delay timer for VS-SEF and single phase low voltage time to active timer.
- Tests were also performed to prove that the unbalance voltage components do not affect the low- voltage scenario.
- As per the logic, the single phase high voltage must be active with unbalance voltage components, such as zero sequence and negative sequence and then combined with SEF for an effective trip.
- Apart from the timers for high voltage and definite time for VS-SEF, the trip time also depends on the unbalance time to active timer.

Evoenergy's Mackenzie feeder network data was represented in an EMTP simulation model. A simplified model was developed for the purpose of analysing the sensitivity of sequence components during downed conductor and vegetation faults while taking into account the worst-case tolerances in current and voltage measurements. The results indicate that the sensitivity of the zero sequence component of the voltage increases marginally with load. The faults at the lateral end towards the load indicate minimum change in the sequence components. However, these factors have been considered with an onerous tolerance factor of the instrument transformers. With improved sensitivity and tolerance of instrument transformers, the practical results would indicate a much better fault detection

performance. This factor has been taken into account while designing the algorithm and its performance during the final high-power laboratory tests.

### **3.4.1.3 Sensitivity observations of VS-SEF operation**

Anegondy, et al., (2019) highlights the following VS-SEF sensitivities from comprehensive laboratory tests:

- The averaged RMS values of the false residual current  $3I_0$  due to measurement tolerances in phase currents varied from 0.14 amperes to 0.32 amperes.
- The non-trip values for heavy inductive loading ranged from 0.81A to 1.11 amperes.
- The trip value of SEF ranged from 1 ampere to 2 amperes.
- The total time to trip varied from 0.164 seconds to 0.405 seconds; the SEF element of the VS-SEF logic is additionally time delayed due to the inverse time logic provided to avoid spurious pick-up.
- The voltage-supervised SEF has three components, a single-phase positive sequence under-voltage unit that will assert only for a fault and would restrain the SEF for normal conditions where the ambient zero sequence conditions would cause a false trip.
- The overvoltage element is conditioned utilising a change in zero sequence voltage or a negative sequence voltage. For ground currents of the order of 1 ampere under balanced conditions, both zero sequence and negative sequence voltage will de-assert and block the logic. For genuine high impedance fault conditions, both these parameters will assert to activate the VS-SEF logic.

Based on the extensive secondary injection testing, EMTP simulation, and primary high power laboratory tests, the pulse-closing voltage-supervised sensitive earth fault detection algorithm appears to have demonstrated an average sensitivity of 1.25 amperes with a clearing time of less than two seconds for either vegetation or downed conductor faults.

Although SEF protection is currently employed in Energy Queensland's distribution network, the new VS-SEF detection method developed by Evoenergy, can be explored and tested further to find its actual effect in Energy Queensland's network..

## **3.5 Fault Resistance**

Abdel-Fattah & Lehtonen (2012) investigates the effect of fault resistance during an earth fault scenario. The investigations include the effect of the fault resistance on the fault current, fault voltage, the transient recovery voltage and the rate of rise of the transient recovery voltage using a realistic 20kV medium voltage network model. It does highlight that in medium voltage overhead networks of utilities across the world, approximately 80% of faults are transient and 80% of faults involve one phase to earth only. The fault current magnitude, fault resistance and the rate of rise of the transient recovery voltage can affect the earth fault characteristics. In unearthed MV network the maximum earth fault current, at zero fault resistance, is limited by the total earth capacitance of the network but for compensated network the maximum earth fault current is limited by the total leakage conductance of the network and compensation branch. The actual earth fault current mainly depends on the maximum value and the fault resistance. For the same network, the maximum value is constant, however the fault resistance on the network earthing conditions and the fault characteristics. The effect of the fault resistance on the fault currents in unearthed and compensated neutral networks is presented in Figure 16 below.

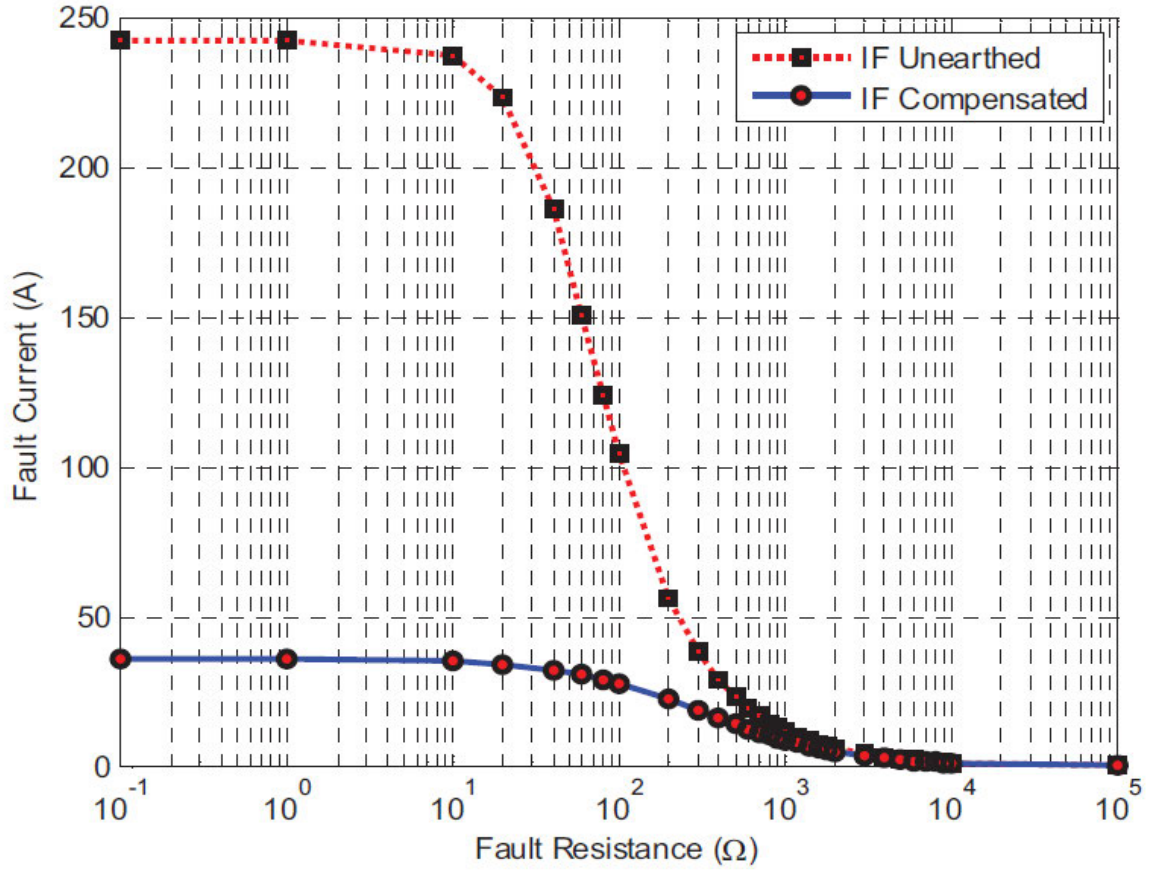

Figure 16: The effect of the fault resistance on the fault currents

It can be seen from Fig.16, that the fault resistance can affect the fault current in both networks. The significant change can be seen in the range of 10-1000  $\Omega$  of the fault resistance. From the simulation results it was seen that the higher values of the fault resistance, starting from 10 $\Omega$ , sharply decreases the transient recovery voltage in unearthed neutral networks, up to 10k $\Omega$ . However, the higher values of the fault resistance, starting from 10 $\Omega$ , sharply increases the transient recovery voltage and rate of rise of the transient recovery voltage in compensated neutral networks, up to 10k $\Omega$ .

Pawlik, et al.(2017) presents a derivation of the closed-form solution to both the earth return self and mutual impedance expressions developed by Carson. During an earth fault on a power system the fault current returns to the source and in a three phase a.c. power system, if the fault is supplied by an overhead line, the current that enters the ground appears to be coupled to the power line by the time varying magnetic field. From an earthing perspective, understanding and defining the behaviour of the earth return current is more significant. The nett magnetic field of the earth return current defines the coupling into auxiliary paths and metallic third party assets, is highly dependent on expressions representing the earth return phenomenon. From the a.c source, the longitudinal electromagnetic field is defined by the current in the wire and the current returning through the earth and must satisfy radial conditions as well as boundary conditions at the both surface of the wire and the earth-air interface. The boundary conditions ensure the longitudinal current in the ground is redistributed into the path of least energy as it propagates through the earth, but result in an additional impedance in the earth return circuit as the time varying magnetic fields inductively energise the half spaces. The increase in

impedance will be a function of the frequency, the soil conductivity, and the height above ground of the conductor.

From Abdel-Fattah & Lehtonen (2012) and Pawlik, et al.(2017) it can be seen that fault resistance plays a major part in determining the value of fault current present. The value of fault current decreases with a higher value of fault resistance and as such also has an effect on voltages on healthy phases. As part of the fault analysis in this research project, various values of fault resistance will be utilised in simulation to analyse it's effects on fault current and also monitor phase voltages during a system fault.

### 3.6 Effect on Voltages during earth faults

Topolanek, et al., (2014) focuses on the operational experience with an automatic system for additional earthing of the faulty or healthy phase during an earth fault. The paper presents the simulation and experimental verification of additional overvoltage on healthy phase during an earth fault in the system. The overvoltage caused by healthy phase earthing in supply substation during an earth fault can lead to insulation breakdown of equipment in affected distribution network. The principle of the method of short-time earthing of the healthy phase is shown in figure 17 below in simplified diagram of the MV supply substation.

Figure 17: Simplified scheme of MV supply substation with automatic systems for additional earthing

The supply transformer station is equipped with three single-pole switches (No.3 in figure 17). Each of these switches can be used to connect any phase to ground thorough a shunt resistor  $R_{SH}$ . This resistor limits the current through the substation earthing systems and its value is  $10\Omega$ . When earth fault occurred in the A-phase, the healthy B-phase which lags the faulty phase is always earthed by automatics for healthy phase earthing for fault localization.

Complete RMS values of phase to neutral voltages recorded during the experimental measurements for the moment when fault location occurred are shown in table 4 below. The percentage values of the voltages, which are related to nominal phase voltage of the network ( $22\text{kV}/\sqrt{3}$ ), are shown in the table below. The results shown below were recorded during experimental measurement, where earth fault was ignited in A-phase and the healthy B-phase was earthed for earth fault location. From the results of this experimental measurement it is apparent that overvoltage in C-phase reached the highest value during localization of low-impedance earth faults. The maximal value of recorded overvoltage in healthy C-phase is 25.65kV. This value reaches to the double value of operation phase voltage on the secondary side of supply transformer. Such high overvoltage could damage insulation strength of C-phase.

Configuration of the network			Type of EF	Phase voltage in the supply substation							
Ex. No.	Capacitive current	Compensation state		U <sub>a</sub>		U <sub>b</sub>		U <sub>c</sub>			
				[kV]	[%]	[kV]	[%]	[kV]	[%]		
0.1	202 A	compensated	solid EF	x	x	x	x	x	x		
1.1	38 A			overcomp.	300Ω/arcing	13,82	109	10,02	79	25,64	202
2.1					13,70	108	10,13	80	25,62	202	
3.1		arcing EF	13,70		108	9,89	78	25,27	199		
4.1		compensated	13,74	108	10,12	80	25,61	202			
5.1			13,80	109	10,06	79	25,65	202			
6.1			3 kΩ	22,84	180	0,14	1	22,97	181		
7.1			1,5kΩ/arcing	x	x	x	x	x	x		
8.1			1,5kΩ/arcing	13,92	110	9,86	78	25,57	201

# Chapter 4 Methodology

## 4.1 Chapter Overview

This chapter outlines the methodology that was utilised to model the earth fault current characteristic of various earthing systems and variance in earth fault values on 11kV feeder model with the incorporation of fault resistance. The background study and literature review has identified a number of key areas to consider when doing this research project which has been incorporated in various phases of this methodology.

## 4.2 Task Outline

The research project mainly consisted of six distinct phases as follows:

1. Literature review
2. Existing and alternate earthing details phase
3. Development and fault modelling phase
4. Investigation into alternate protection phase
5. Investigation into new earth fault detection technology phase
6. Analyse actual phase to ground fault data from field

Major details and contents of each project phase are outlined in Tables 5 to 8. The different phases of the research project were completed simultaneously at times in-order to complete the entire task successfully and be able to meet all required submission deadlines.

### 4.2.1 Phase 1 – Literature review

This phase mainly involved performing extensive literature research to identify what has been done in this area so far and the remaining area of knowledge gap. There have been a vast number of researches done around this area but it has not been adequately established regarding the detection of low values of earth fault current.

### 4.2.2 Phase 2 – Existing and alternate earthing

Phase 2 of the research project as shown in Table 5 involved carrying out study and analysis of existing earthing systems. Earth fault values differ depending on which type of earthing system is being utilised at a particular distribution substation therefore the benefits and challenges of existing earthing system was looked at in this phase. It also involved doing analysis and detail study of alternate earthing system as highlighted in literature review. Energy Queensland's network has a vast number of legacy networks with different designs and equipment so investigating into alternate earthing systems to be integrated into these networks was looked at as part of this study. Limitations in existing earth fault design currently implemented in Energy Queensland's distribution network such as detection of high impedance earth faults and also seeking information regarding different forms of earth fault protection utilised by other power utilities in Australia was also carried out in this phase.

Task Designation	Task Descriptions
Phase 2	Existing and Alternate Earthing details Phase
2A	Existing Earthing Details <ul style="list-style-type: none"> <li>Study the existing earthing models of Energy Queensland's distribution network</li> <li>Note the challenges, advantages and disadvantages of existing earthing systems</li> </ul>
2B	Earth Fault Protection Design <ul style="list-style-type: none"> <li>Understanding the limitations and challenges of existing earth fault protection utilised in Energy Queensland's distribution network</li> <li>Investigate the various forms of earth fault protection currently used by distribution network service providers within Australia to see if it would be beneficial and suitable to Energy Queensland's distribution network</li> </ul>
2C	Alternate Earthing Systems <ul style="list-style-type: none"> <li>Investigate the availability of alternate earthing systems being utilised by other power utilities</li> <li>Perform analysis of the alternate earthing systems to see it's viability and suitability to Energy Queensland's distribution network</li> </ul>

Table 5: Methodology – Phase 2

### 4.2.3 Phase 3 – Earth fault modelling

Phase 3 of the research project mainly involved earth fault modelling on 11kV feeders at Ergon Energy's Woodstock South (WOSO) substation. The substation as shown in figure 18 consisted of a 66/11kV 6.3MVA power transformer which was feeding into three 11kV feeders. The neutral or star connection on 11kV side of the power transformer was solidly earth.

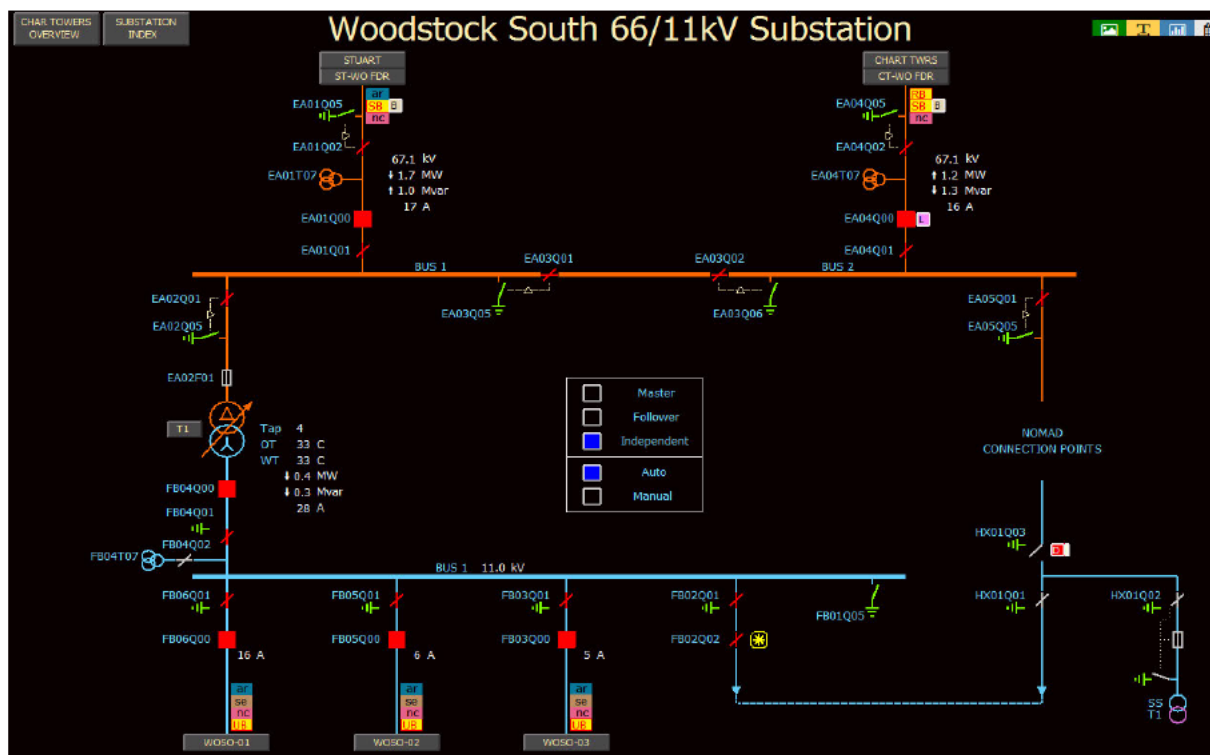

Figure 18: Woodstock South 66/11kV Substation

Woodstock South substation model was obtained from the master database and validated with the current network configuration. Table 6 below outlines the detailed earth fault analysis as performed in phase 3 of the research project. Dig-Silent Power-factory software package was utilised to carry out the analysis. Results of the study for various simulated scenarios highlighted in table 6 below were extracted from the software package and copied onto Microsoft excel to validate and analyse the results.

<b>Task Designation</b>	<b>Task Descriptions</b>
Phase 3	Fault Modelling Phase
3A	<p>Network Models</p> <ul style="list-style-type: none"> <li>Woodstock South network model was obtained from the master database model.</li> <li>The network model as shown in figures 19 and 20 was verified with the operating schematic diagram as per Appendix C to ensure that the model was correctly configured with correct normally open points and accurate protective device.</li> </ul>
3B	<p>Data Validation</p> <ul style="list-style-type: none"> <li>The maximum and minimum source impedance for WOSO was obtained and entered into the external grid in Power factory model for earth fault simulations</li> <li>There were a number of errors as Appendix D flagging up in WOSO power factory model, hence all needed to be corrected before the analysis could be executed. Some of these included wrong transformer types, and incorrect overhead line data.</li> </ul>

Introduced fault impedance in the network of 10 to 50ohms.</li> <li>Measured fault current and phase voltages in all scenarios to see the behaviour of fault current and effect on voltages on faulted and un-faulted phases.</li> <li>Simulated a 6ohm NEX at source on 11kV neutral to introduce impedance grounding.</li> <li>Performed system normal analysis with maximum and minimum source impedance analysis with zero ohms fault impedance</li> <li>Performed system normal analysis with maximum and minimum source impedance analysis with varying fault impedance. Introduced fault impedance in the network of 10 to 50ohms.</li> <li>Measured fault current and phase voltages in all scenarios to see the behaviour of fault current and effect on voltages on faulted and un-faulted phases.</li> <li>Checked clearing times achieved by existing protection devices for minimum earth faults on each feeders.</li> </ul>

*Table 6: Methodology – Phase 3*

Figure 19 below represents the geographical layout of the three 11kV distribution feeders utilised in earth fault analysis emanating from Woodstock South substation.

*Figure 19: Geographical layout of 11kV feeders at WOSO*

Figure 20 below represents the Woodstock South substation model in DigSilent Power Factory. The maximum and minimum values of source impedance and fault resistance were varied in external grid during the earth fault analysis. There was no other earth fault contribution from other sources such as embedded generation in this model. Analysis was performed on each feeder separately so that results could be sorted out easily.

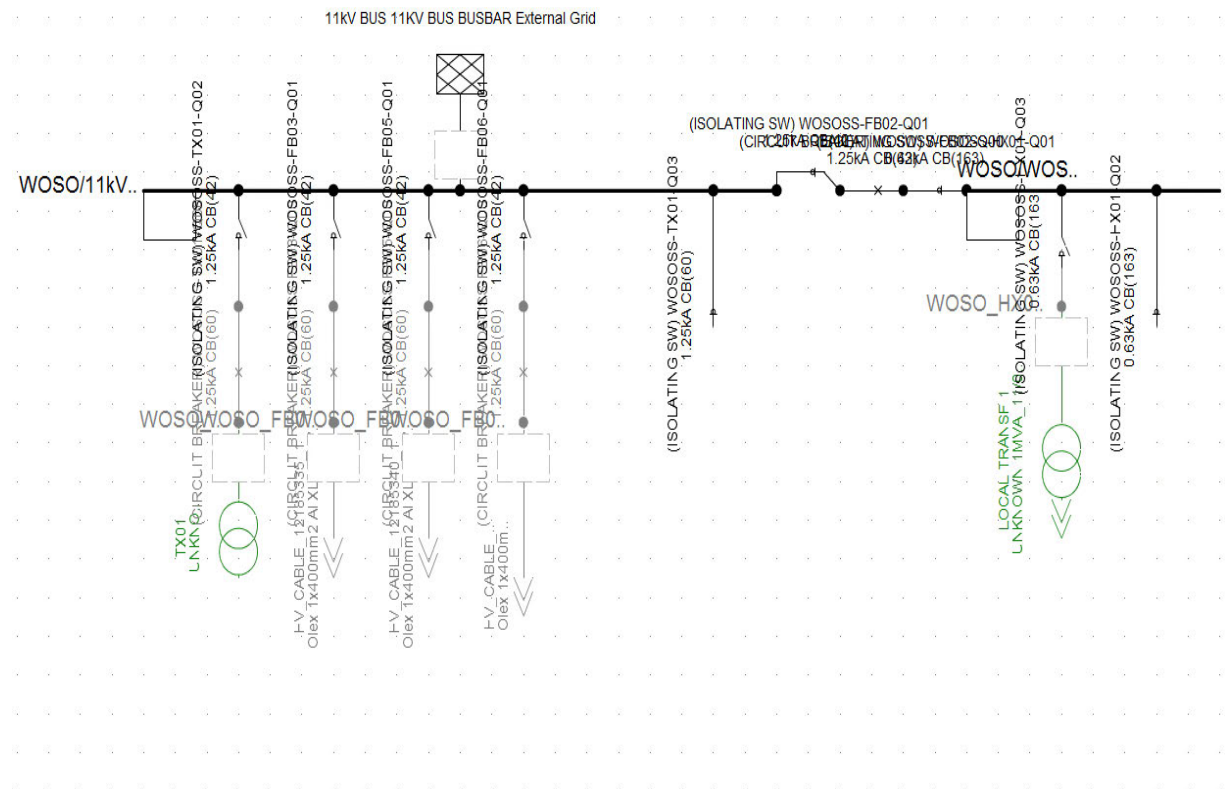

Figure 20: WOSO model in Dig-Silent Power Factory

#### 4.2.4 Phase 4 – Alternate protection

Phase 4 as highlighted in Table 7 below involved liaising with suppliers and manufactures to see if there were alternate forms of protection available in their protective devices that could assist in earth fault detection.

<i>Task Designation</i>	<i>Task Descriptions</i>
Phase 4	Investigation into Alternate Protection Phase
4A	Alternate Protection <ul style="list-style-type: none"><li>Research and investigate alternate protection functions currently available in protective devices from suppliers / manufacturers which can be utilised for detecting earth faults.</li></ul>
4B	Suitability of Alternate Protection <ul style="list-style-type: none"><li>Determine the advantages and disadvantages of the alternate protection function to Energy Queensland's distribution network. Need to ensure that alternate protection does not introduce new issues in the network.</li></ul>

*Table 7: Methodology – Phase 4*

#### 4.2.5 Phase 5 – New detection technology

Phase 5 as highlighted in Table 8 below involved liaising with suppliers and manufactures to see if there were new technologies available in the today's world that could assist in earth fault detection.

<i>Task Designation</i>	<i>Task Descriptions</i>
Phase 5	Investigation into new Technologies Phase
5A	New Detection Technologies <ul style="list-style-type: none"><li>Research and investigate the availability of new technologies that may provide better earth fault detection capabilities</li></ul>
5B	Viability of New Technology <ul style="list-style-type: none"><li>Determine the advantages and disadvantages of the new detection technology to Energy Queensland's distribution network. Need to ensure that new detection technology does not introduce new issues in the network.</li></ul>

*Table 8: Methodology – Phase 5*

#### 4.2.6 Phase 6 – Analysis of actual fault data from field

An actual phase to ground fault data was obtained from protective device's in the field after a high impedance phase to ground fault occurred on a 11kV feeder overhead feeder. The fault had very low values of fault current and the duration of fault current was not long enough for immediate SEF protection to isolate this fault. Waveforms and event records were retrieved from the field devices by field staff. Relevant protection relay applications were utilised to analyse the waveforms and records retrieved from protective devices as more than one protective device was in the protection scheme and had detected the fault for this particular event.

### 4.3 Interpretation and Analysis of Results

Interpreting and analysing results was a major aspect of this research project. Therefore, it was extremely important that the data was precisely and accurately recorded. The network modelling process in Power-Factor fault modelling software involved simulating a number of fault scenarios and permutations and therefore lot of results needed to be accurately recorded. Microsoft excel was used as a tool to record the results in tabulated form and then represent those data in graphical format. Part of the research also involved correspondence with power utilities and various protection relay manufacturers. It was ensured that if any data was received, it was correctly interpreted and also verified with the sender so that there was no ambiguity.

### 4.4 Resource Requirements

The majority of the project resources utilised during the research project were software resources, and were either privately owned, or were obtained from Energy Queensland.

The following table 9 outlines the list of software and equipment which was used during the duration of the research project:

<i>Item</i>	<i>Quantity</i>	<i>Source</i>	<i>Cost</i>	<i>Comment</i>
PC with Microsoft Windows	2	Energex & Student	Nil	Required work PC to access systems and personal laptop for project write up and research.
Microsoft Word	1	Student	Nil	Report Writing
Microsoft Excel	1	Student	Nil	Data Entry
IPS database	1	Energex & Ergon	Nil	Obtain protection settings
Power On Web view	1	Energex	Nil	Network Overview
POWERFACTORY	1	Ergon	Nil	Network Modelling / Fault Analysis

*Table 9: List of Software and Equipment required*

### 4.5 Quality Assurance

The following procedure was utilised to ensure that all simulation and analysis was performed and results recorded to the highest possible accuracy:

1. Fault analysis results obtained from existing earthing systems. This was validated between different substations to ensure that there were not inconsistencies in results.
2. Data (conductor, cable and earthing details) used in modelling of alternate earthing systems was confirmed and validated using other data storage systems used in Energy Queensland.
3. Any equipment details or data obtained from suppliers / manufactures was validated to ensure that it did not consist of errors which would affect the simulation and analysis process.
4. Continuous feedback was obtained from USQ project supervisor to ensure that the research study meets the set criteria.

5. Project supervisor from Energy Queensland was informed so that there was no oversight in any simulations and analysis.

The methodology utilised in this research project resulted in successful completion of this study which will also be beneficial to Energy Queensland.

## **4.6 Consequences and Ethics**

As per competency standard set by Engineers Australia, Professional Engineers are required to take responsibility for engineering projects and programs in the most far-reaching sense. Professional Engineers are responsible for interpreting technological possibilities to society, business and government; and for ensuring as far as possible that policy decisions are properly informed by such possibilities and consequences, and that costs, risks and limitations are properly understood as the desirable outcomes. There are severe penalties issued to professionals if breach is found in engineering practices.

In accordance with the Engineers Australia document *Our Code of Ethics (Engineers Australia n.d.)*, it is expected that engineering professionals will act in an ethical manner, addressing safety and sustainability considerations. To ensure that the research project was conducted in a safe, sustainable and ethical manner, continuous analysis of the consequential effects of the research project was undertaken. Additionally, the possible effects that the research project could have after the project has been concluded were examined to ensure that any foreseeable consequences are acceptable.

### **4.6.1 Risk Assessment**

A risk assessment was performed to address safety concerns and mitigate any risk to personnel involved in this research project. The risks were categorised, with appropriate control measures developed as per Appendix B. By thoroughly assessing, controlling and reviewing risks at all times, project safety was maintained at high standards during the duration of the research study. This ensured that due diligence in meeting safety requirements to me and others involved in this project was always at the highest level. Majority of research work and study was required to be carried out within an office environment, therefore there was minimal risk to personnel. Also in doing this research study which had an aim of improving the safety in distribution power network which the society and communities will benefit from.

### **4.6.2 Peer Review**

During the process of completing this research project there were occasions whereby numerous feedback was obtained from peers. This also included engineering personnel from Energy Queensland and also fellow colleagues from Engineering Discipline at USQ. The peer review process provided mutual benefits to the researcher and the peer group. The peer group will gain knowledge from the research to initiate or support further studies, and the researcher benefits by improving in areas of research identified by other professionals. By having the dissertation peer reviewed also meets the guidelines of Engineers Australia *Our Code of Ethics (Engineers Australia n.d.)*. The guideline states “2. *Practice Competently – 2.1 Maintain and develop knowledge and skills – seek peer review – support the ongoing development of others.*”

### 4.6.3 Sustainability

The proposed alternate earthing systems and new earth fault detection techniques was made in view of the economic and viability to Energy Queensland's distribution network. With electricity prices being continuously a talking point for society and political parties, the cost of implementing new technology was carefully thought off. The benefits needed to outweigh the costs involved. In doing a detail sustainable study will meet the guidelines of Engineers Australia *Our Code of Ethics* (Engineers Australia n.d.). The guideline states "4. *Promote Sustainability – 4.2 Practice engineering to foster the health, safety and wellbeing of the community and the environment – incorporate social, cultural, health, safety, environmental and economic considerations into the engineering task.*"

# Chapter 5 Findings of Earthing Systems and EF Protection

## 5.1 Chapter Overview

This chapter highlights the findings of benefits and challenges of existing earthing systems utilised in Energy Queensland's distribution power network and also the earth fault protection employed by some of the distribution power utilities in Australia.

## 5.2 Benefits and challenges of existing earthing systems

### 5.2.1 Solidly Earth

The main benefits include:

- Highest magnitude of phase to earth fault currents and simple earth fault protection can be utilised in most places.
- Over-voltages during earth faults are the lowest (around 0.8 times phase to phase voltage).
- Arcing ground faults cannot occur as the short circuit current is much larger than the capacitive charging and eliminates its influence.
- Lowest capital and maintenance cost as there is no need for extra equipment to be installed between the transformer neutral terminal and substation earth grid.
- Simple to understand by operational personnel.

The main challenges include:

- Presence of high fault currents can cause severe damage to system plant.
- High fault currents present severe flash and shock hazards.
- High fault currents can lead to interference in communication circuits in around the vicinity of power cables and overhead power lines.

### 5.2.2 Resistance / Reactance Earthing – NER's & NEX's

The main benefits include:

- Low magnitude of phase to earth fault currents hence reducing the risk of severe flash hazards.
- Less likelihood of equipment damage as earth fault current is greatly reduced.
- Safer for work personnel and general public in-terms of reduction in step and touch potential.

The main challenges include:

- High values of transient over-voltages during faults. This needs to be considered carefully in design stages, the rating of surge arrestors and short-time thermal current ratings of underground cable screens and earthing conductors.
- High capital and maintenance cost as equipment needs to be installed between the transformer neutral and substation earth which also needs to be maintained for the life of the equipment. Also high cost of retrofitting on the networks that are not designed to handle the overvoltages.

### 5.3 Results of Analysis

The following table 10 shows earth fault current and phase voltage values for a simulation of A-phase to ground fault at WOSO 11kV bus with different earthing systems.

Earthing Type	Fault Current (A)			Phase Voltages (kV)		
	A-Phase	B-Phase	C-Phase	A-Phase	B-Phase	C-Phase
Solidly	3212	0.000	0.000	0.000	7.0315	6.3933
6ohm NEX	857	0.000	0.000	0.000	10.631	10.2431
3ohm NER	1752	0.000	0.000	0.000	8.2352	11.7171

Table 10: Earth Fault Analysis at WOSO 11kV Bus

Figure 21 below shows the difference in fault current values for A-phase to ground fault simulation on WOSO-01 11kV feeder with different earthing system. This was simulated to look at the difference in fault current values with different earthing systems.

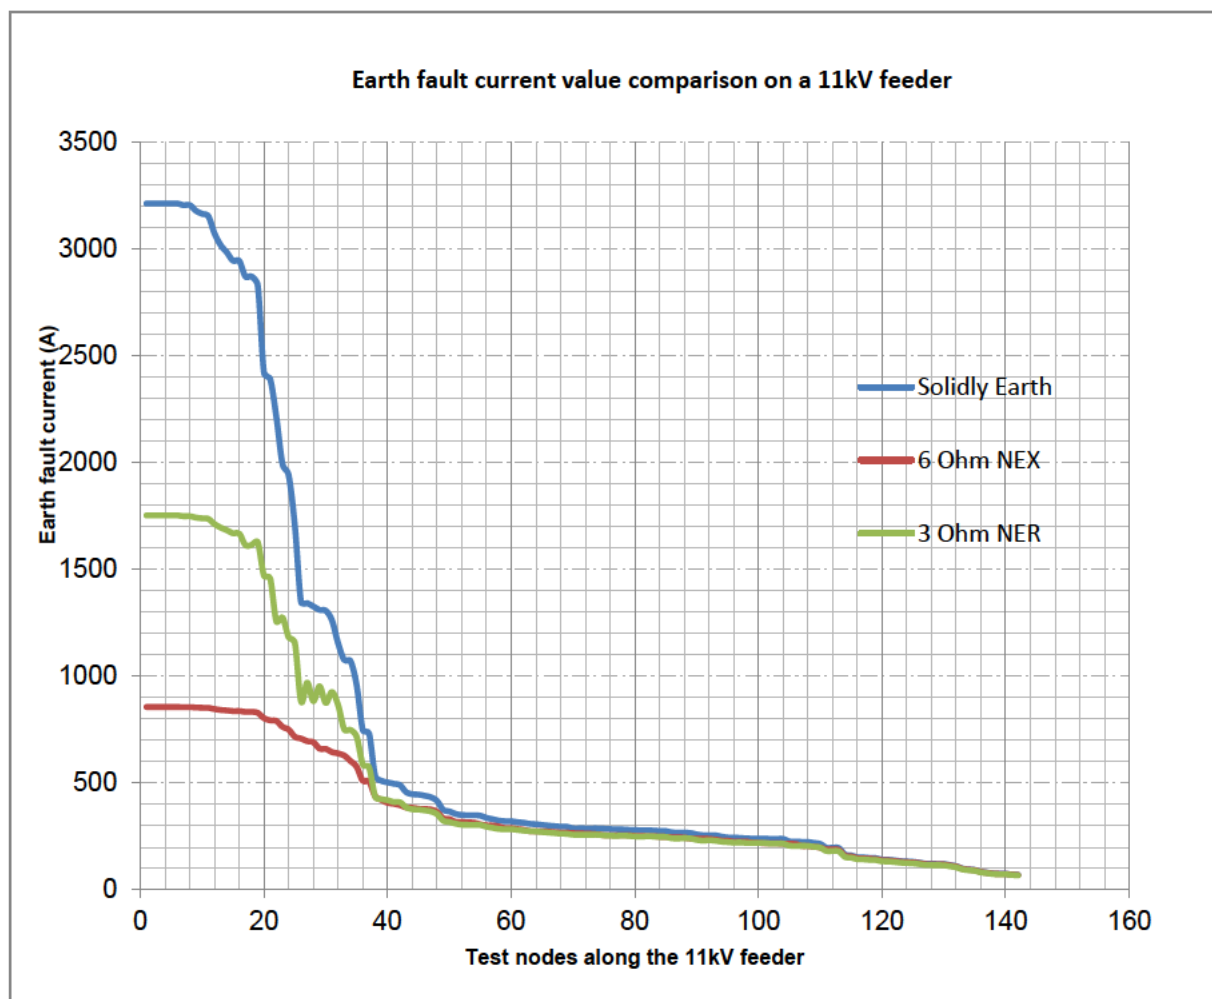

Figure 21: Current Values for Earthing System Analysis on WOSO-01

Figure 22 below shows the difference in voltage values for A-phase to ground fault simulation on WOSO-01 11kV feeder with different earthing system. The voltages on faulted and unfaulted phase were looked at to understand the effects of earth fault currents on system voltages.

Figure 22: Voltage Values for Earthing System Analysis on WOSO-01

From the above results and analysis it can be seen that highest value of fault current (3212A) is obtained from a solidly earth system. The fault current drops accordingly to the value of resistance or reactance earth system. Phase to phase voltage is high on a resistance or reactance earth system as seen from the results / analysis above as compared to a solidly earth system. The increase in steady state and transient overvoltage caused by impedance earth during an earth fault on the sound phase can result in the fault spreading to other phases. The components and hardware used in the system has to be adequately rated to withstand these transient over-voltages to prevent continuous equipment damages during a fault scenario in other parts of the network. The full extract of results is as tabulated in Appendix E.

## 5.4 Earth fault protection used by other Australian utilities

As part of the research, few distribution power utilities were contacted to find out about their approach to earth fault protection and if they are introducing new techniques, technologies or schemes that can be beneficial to Energy Queensland's distribution power network.

### 5.4.1 SA Power Networks

SA Power Networks is the sole electricity distributor in South Australia, delivering electricity from high voltage transmission network connection points, through a network of powerlines to residential and business customers. The distribution power network is very similar to Energy Queensland's network with very long radial feeders. SA Power Networks faces similar issue in detecting low values of earth fault. Currently they have been employing the following around earthing systems and earth fault detection:

- Apart from CBD, all other distribution power system is solidly earth.
- Installed few fault current limiters but due to excessive maintenance issues had to stop installing them.
- Issues of increasing fault levels in the CBD due to embedded generation and hence have started to install NER's in zone substations to restrict earth fault levels.
- Encounter issues in detecting low values of earth fault on long distribution feeders and hence only utilising SEF protection. SEF is generally set to 5A, 5sec and was introduced in 1980's to improve safety. Longest SEF time that is acceptable is under 5sec. Protection grading margin for SEF protection will be allowed but the aim is always to stay under 5sec.
- Have also started introducing SEL751 protection relays as new form of digital protection relays. Challenging part is obtaining low SEF pick up settings due to minimum setting of relay with respect to CT ratio chosen.

SA Power Networks are further interested in exploring high speed clearing device times so that faults can be cleared more quickly to avoid bush fires and catastrophic network damages. Suggestions to manufacturers to develop technology in reclosers so that main trip can be bypassed during bush fire season to a much high speed tripping device.

### 5.4.2 Western Power

Western Power is a Western Australian State Government owned corporation with the purpose of connecting people with electricity in a way that is safe, reliable and affordable. Their network covers a very large area of 255,064 square kilometres from Kalbarri in the north, to Kalgoorlie in the east and Albany in the south, including the Perth metropolitan area. Unlike all other major urban areas of Australia which are covered by a series of interconnected networks, Western Power's network is isolated and self-contained. With very long radial distribution feeders in the country side, they face similar issue of detecting low values of earth fault. Currently they have been employing the following around earthing systems and earth fault detection:

- Impedance earth in the metro region whilst solidly earth system utilised in country side substations.
- SEF and normal IDMT earth fault protection are utilised to protect feeders against earth faults occurring in the network.

- Earth fault compensation is also used widely in Western Powers network. The idea of earth fault compensation is to cancel earth capacitance by equal inductance, a so called Petersen coil connected to the neutral, which results in a corresponding decrease in earth fault currents as shown in figure 23. Instead of one large controlled coil at the HV/MV substation, in rural networks it is possible to place inexpensive small compensation equipment, each comprising a star-point transformer and arc-suppression coil.

Figure 23: Earth fault in a network with a compensated neutral

In figure 23, the circuit is a parallel resonance circuit and if exactly tuned, the fault current has only a resistive component. This is due to the resistances of the coil and distribution lines together with the system leakage resistances ( $R_{LE}$ ). Often the earthing equipment is complemented with a parallel resistor  $R_p$ , the task of which is to increase the ground fault current in order to make selective relay protection possible.  $I_t = I_L - I_P$  is the current of the suppression coil and a parallel resistor,  $I_{L2c}$  and  $I_{L3c}$  are the capacitive currents of the sound phases, and  $I_{ef} = I_{L2c} + I_{L3c} - I_t$  is the earth fault current at the fault point.

Figure 24 below represents the equivalent circuit for earth fault compensated network.

Figure 24: Equivalent circuits for the earth fault compensated network

### 5.4.3 Endeavour Energy

Endeavour Energy is responsible for the safe and reliable supply of electricity to 2.4 million people in households and businesses across Sydney's Greater West, the Blue Mountains, Southern Highlands, the Illawarra and the South Coast. It is 50.4 percent owned by an Australian-led consortium of long-term investors in the private sector and the remaining 49.6 percent is held by the State of NSW. The network topology consists of a mixture of overhead lines and underground cables with radial and interconnected network. They face similar issue of detecting low values of earth fault. Currently they have been employing the following around earthing systems and earth fault detection:

- All 11kV networks are solidly earth.
- 22kV network utilise NER to restrict earth fault current to around 1000A.
- Normal earth fault IDMT protection is mostly utilised together with SEF protection. SEF is set to a minimum of 4A, 5sec and if protection grading is required for discrimination purposes with upstream protective device, then 1sec grading is only allowed between devices while current is always maintained to a value of 4A.
- Core-balance CT's are utilised in high risk bush fire areas. It is a single CT of ring type, through the centre of which is passed cable that forms the primary winding. An earth fault relay, connected to the secondary winding, is energised only when there is residual current in the primary system. The advantage in using this method of earth fault protection lies in the fact that only one CT core is used in place of three phase CTs whose secondary windings are residually connected. In this way the CT magnetising current at relay operation is reduced by approximately three-to-one, an important consideration in SEF relays where a low effective setting is required. The CT's utilised are very accurate at low levels of fault current which can see down to 0.1Amps of primary current and it is only enabled on total bush fire days and only set to 1Amp pickup.

The correspondence and details obtained from distribution power utilities similar to Energy Queensland, it can be seen that similar issues in the area of earth fault detection is faced by other power utilities as well. Commonly SEF protection has been utilised with varying detection and time delays depending with their practices and philosophies. The utilities are keen in the development of algorithms and devices by manufacturers that can play a vital role in earth fault detection. Some of the utilities are coming up with their own invention and techniques which can assist in achieving better detection capabilities.

# Chapter 6 Earth Fault Analysis Results

## 6.1 Chapter Overview

This chapter focuses on discussing the results of earth fault analysis which was carried out on 11kV feeders out of WOSO substation, looking into fault clearing times of protective devices and also analysis of an actual phase to ground fault with low values of fault current.

## 6.2 Earth fault analysis discussion

A – Phase to ground fault was simulated on all three 11kV feeders out of WOSO substation. There were two scenarios of source impedance considered:

- Maximum source impedance with system normal
- Minimum source impedance with 66kV Stuart feeder out of service

The following simulations were performed on the feeders:

- Solidly earth system with maximum and minimum source impedance
- Solidly earth system with maximum and minimum source impedance plus fault resistance
- NEX earth system with maximum and minimum source impedance
- NEX earth system with maximum and minimum source impedance plus fault resistance

From the results of earth fault analysis, it can be seen that the highest value of current is obtained from a solidly earth system and is highest at the source substation. Due to the comparatively high reactance of overhead lines, the attenuation of fault power along the line is high and the current values resulting from faults at points remote from the substation are considerably reduced as seen in figure 25 below.

In table 11 below, a comparison of earth fault values for WOSO-01 11kV feeder at the same nodes for the various earthing type simulations are represented. The maximum value of fault current recorded was at the substation busbar so a comparison between the different scenarios was done at that node. The minimum value was recorded at the remote end of the feeder. The same node was considered for comparison of results to accurately see the differences in fault current values for each of the fault scenarios.

<i>Earthing Type</i>	<i>Fault Current (A)</i>	
	<i>Maximum</i>	<i>Minimum</i>
Solidly + Max Source Impedance	3212	70
Solidly + Min Source Impedance	2014	27
Solidly + Max Source Impedance + 50ohm Rf	139	47
Solidly + Min Source Impedance + 50ohm Rf	124	23
6ohm NEX + Max Source Impedance	856	70
6ohm NEX + Min Source Impedance	704	27
6ohm NEX + Max Source Impedance + 50ohm Rf	137	47
6ohm NEX + Min Source Impedance + 50ohm Rf	122	23

Table 11: Earth Fault Analysis of WOSO-01 11kV Feeder

From the fault current values in table 11, it can be seen that for a solidly earth system and a system with 60hm NEX, the fault values are significantly high at source while the values are significantly small at the remote end or as the fault moves away from the source along the feeder. Since the driving voltage is high and negligible impedance at the source, it contributes to high values of earth fault current at the source. As the fault moves away from the source the voltage drops and impedance increases along the line hence the fault current drops. Also it can be seen from figure 23 below that regardless of the earthing system and fault impedance, the fault values at the very remote end of the feeder are very much similar. This is due to the fact that since the fault has moved so far away from the source and adding impedance no longer has effect in the fault current. The concerning part however is the small values of fault current at remote ends or along the feeder, if more fault resistance is added which effectively refers to high impedance faults, these values will drop more and will become challenging for protective devices to detect.

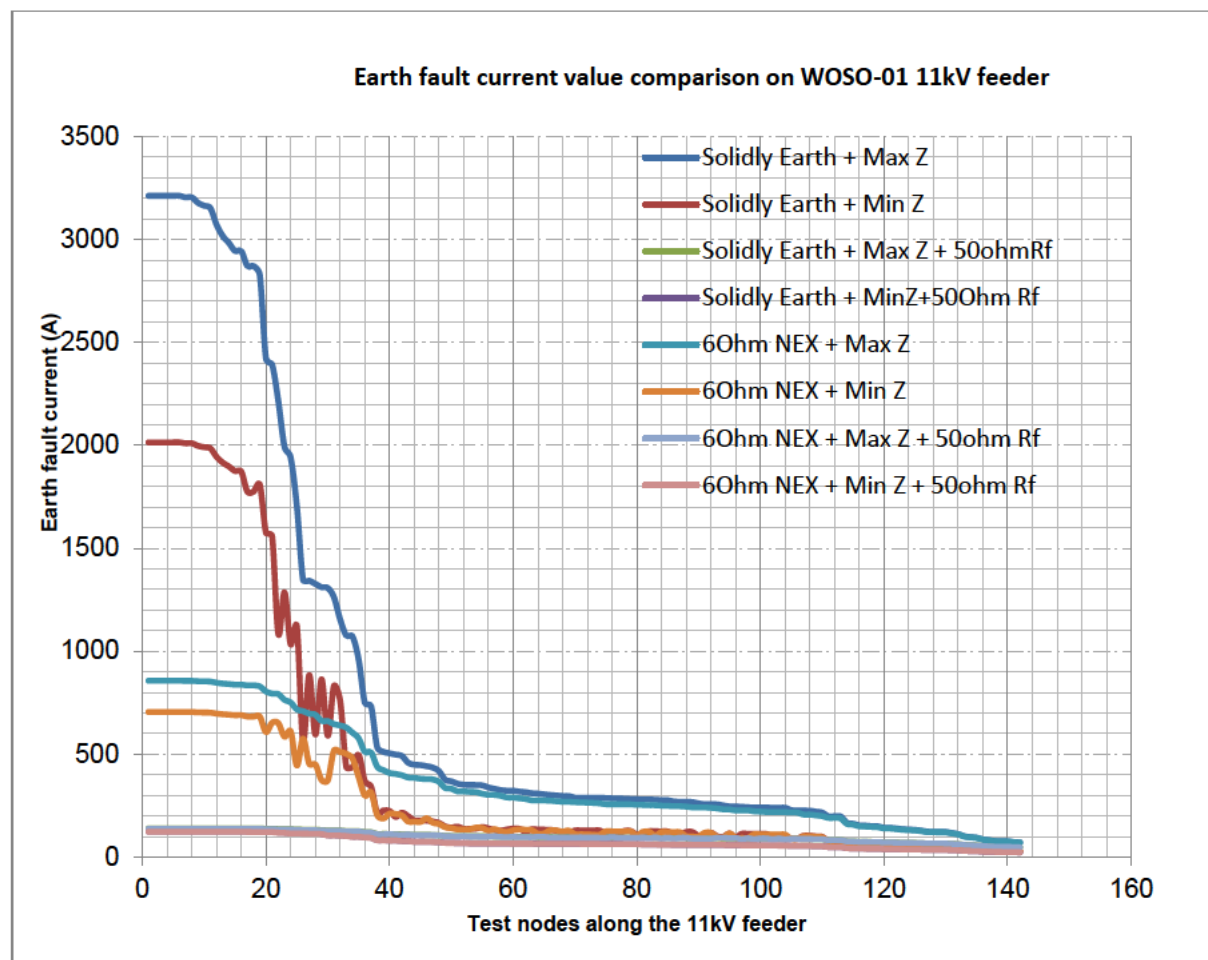

Figure 25: Earth fault current value comparison on WOSO-01 11kV feeder

The results of the analysis of various scenarios are represented in graphical format as shown in figures 26 to figures 33.

Figure 26 below represents the result of analysis for a solidly earth system with maximum source impedance and no fault resistance in the network. Maximum source impedance is obtained whereby the system is operating in a system normal status with both 66kV Stuart feeder out of service. The results are for all the three feeders out of Woodstock substation. From the results it can be seen that maximum value of earth fault current (3212A) for each of the three feeders is at the substation. The minimum value of fault current differs in each of the feeders due to the length and construction of the feeder. The minimum value of fault current recorded for WOSO-01 11kV feeder was 70A in comparison to WOSO-02 feeder which was 131A and WOSO-03 feeder was 55A.

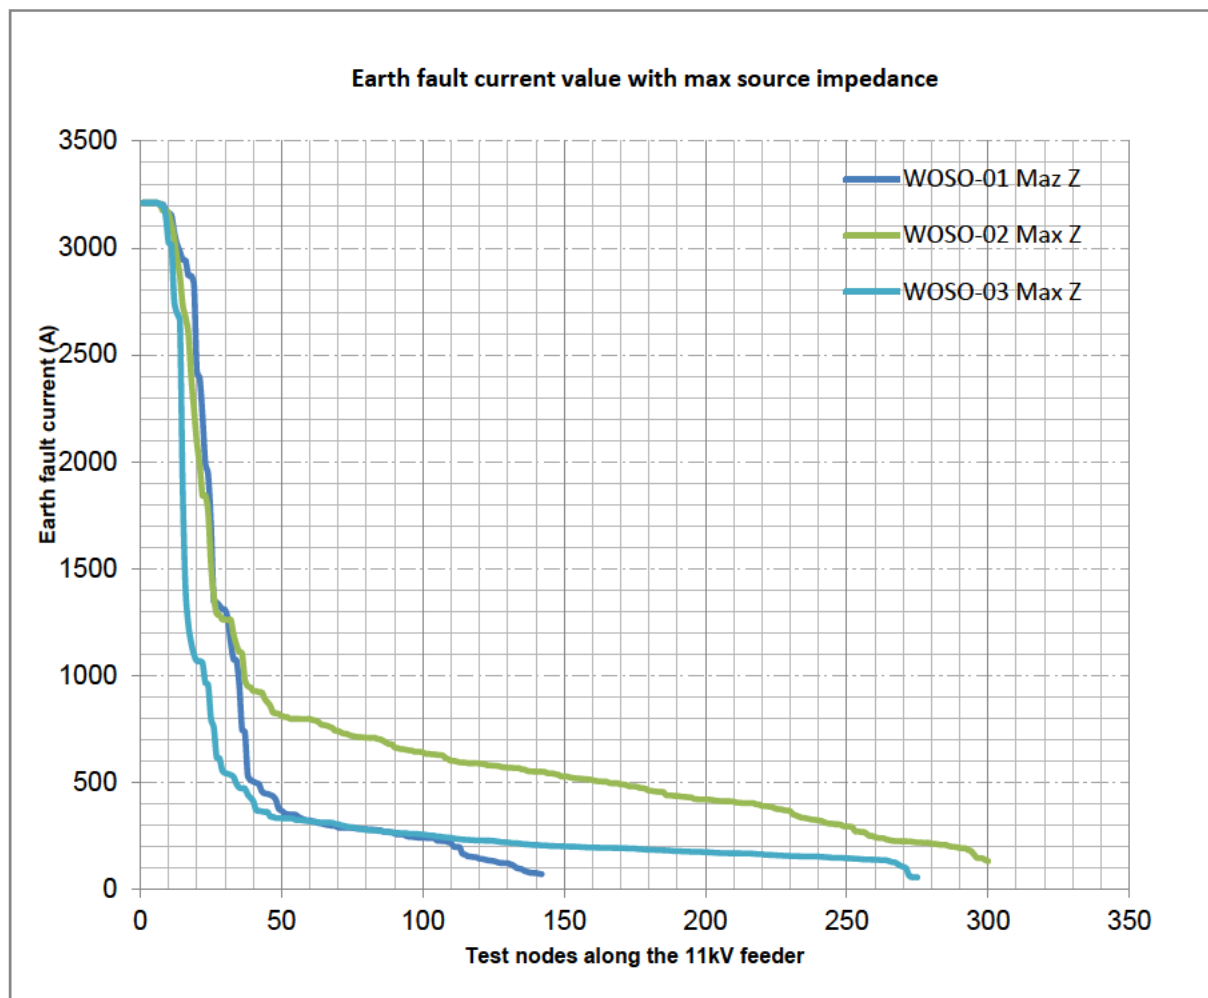

Figure 26: Solidly earth with max source impedance and no fault resistance

Figure 27 below represents the result of analysis for a solidly earth system with minimum source impedance and no fault resistance in the network. Minimum source impedance is obtained whereby the system is operating in an abnormal status with 66kV Stuart feeder out of service. From the results it can be seen that maximum value of earth fault current was 2014A for each of the three feeders at the substation in comparison to the previous scenario which had fault current of 3212A at the same node. The minimum value of fault current recorded for WOSO-01 11kV feeder in this case was 27A in comparison to WOSO-02 feeder which was 56A and WOSO-03 feeder was 23A. It was also noted that WOSO-02 feeder had quite a bit of variation in magnitude of earth fault current.

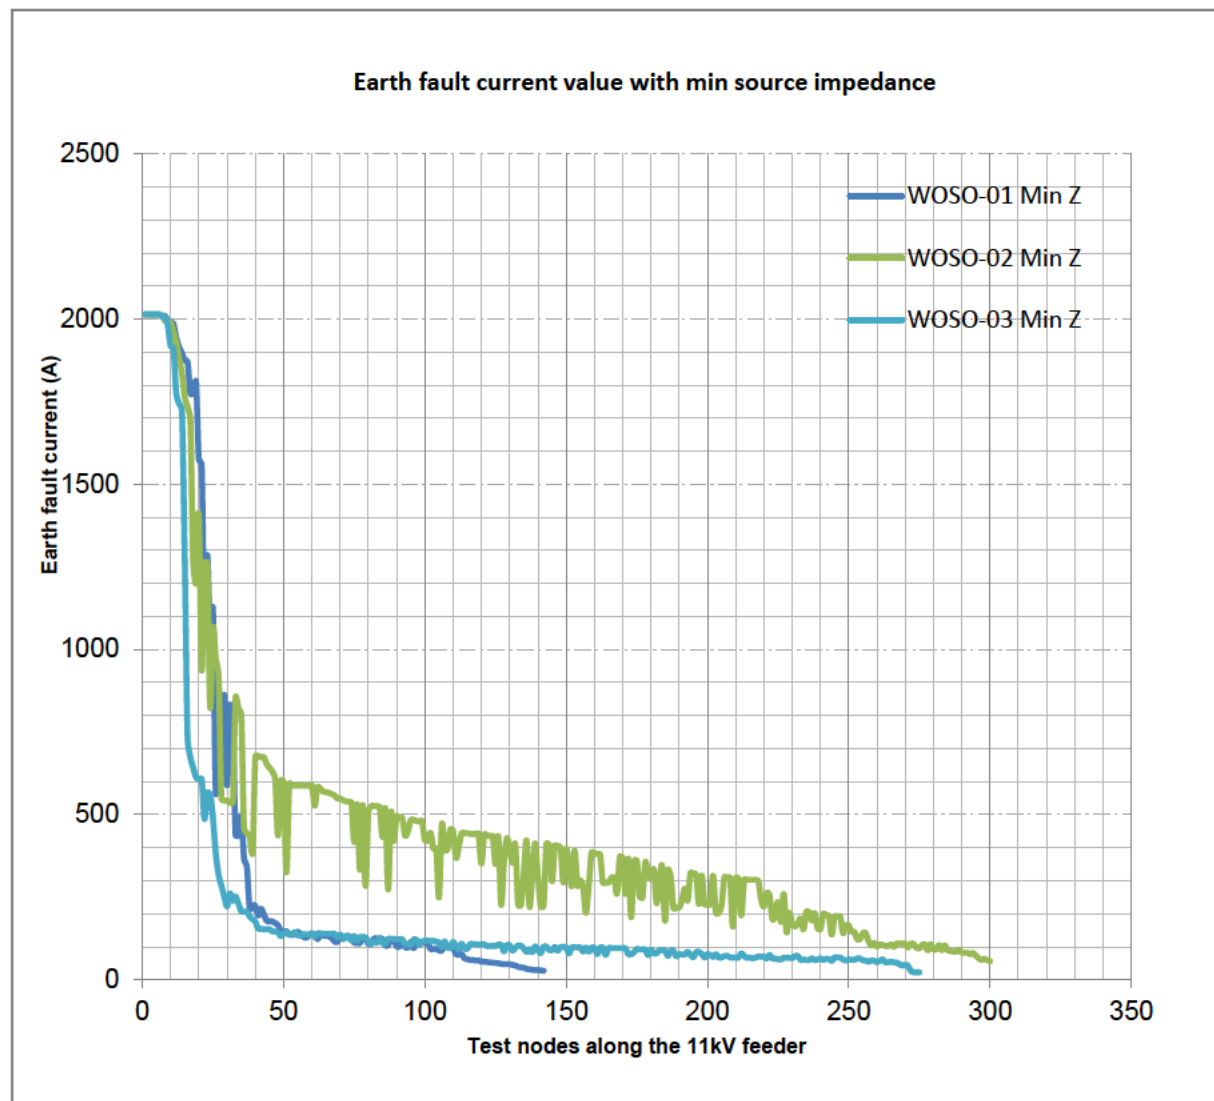

Figure 27: Solidly earth with min source impedance and no fault resistance

Figure 28 below represents the result of analysis for a solidly earth system with maximum source impedance and 50Ω fault resistance in the network. A value of 50Ω fault resistance was introduced in the circuit to see how the earth fault current value varied. From the results it can be seen that maximum value of earth fault current drops quite significantly to only 139A for each of the three feeders at the substation in comparison to figure 26 where the fault current at the same node was 3212A. The minimum value of fault current recorded for WOSO-01 11kV feeder was 47A in comparison to WOSO-02 feeder which was 69A and WOSO-03 feeder was 40A. When comparing these minimum values of earth fault current to figure 26, it can be noted that there was a reduction of around 30% in earth fault current when fault resistance was introduced in the analysis.

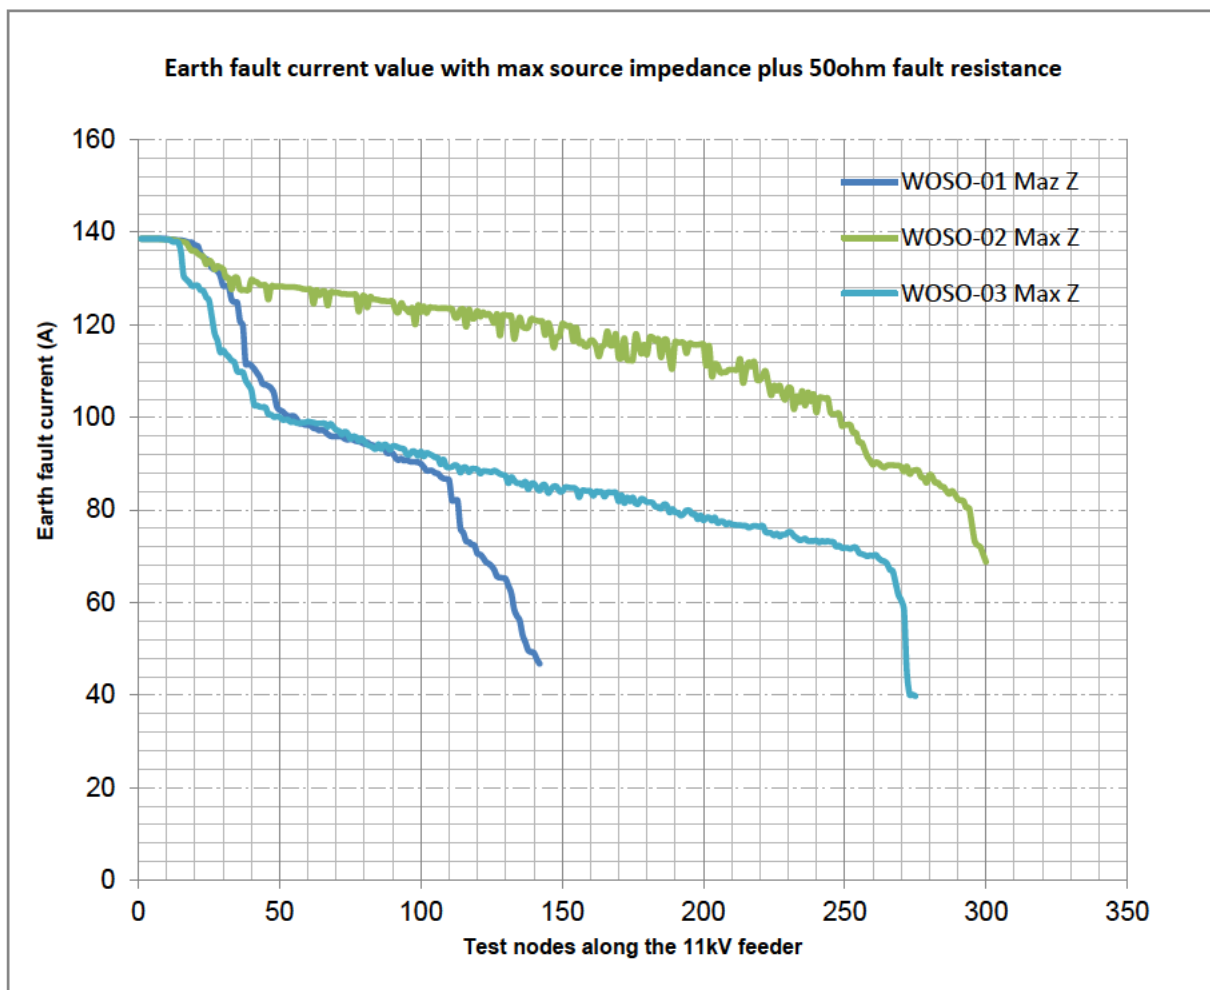

Figure 28: Solidly earth with max source impedance plus 50ohm fault resistance

Figure 29 below represents the result of analysis for a solidly earth system with minimum source impedance and 50Ω fault resistance in the network. From the results it can be seen that maximum value of earth fault current drops quite significantly to only 124A for each of the three feeders at the substation in comparison to figure 27 where the fault current at the same node was 2014A. The minimum value of fault current recorded for WOSO-01 11kV feeder was 23A in comparison to WOSO-02 feeder which was 39A and WOSO-03 feeder was 19A. When comparing these minimum values of earth fault current to figure 27, it can be noted that there was a only a small reduction of few Amps in earth fault current when fault resistance was introduced in the analysis.

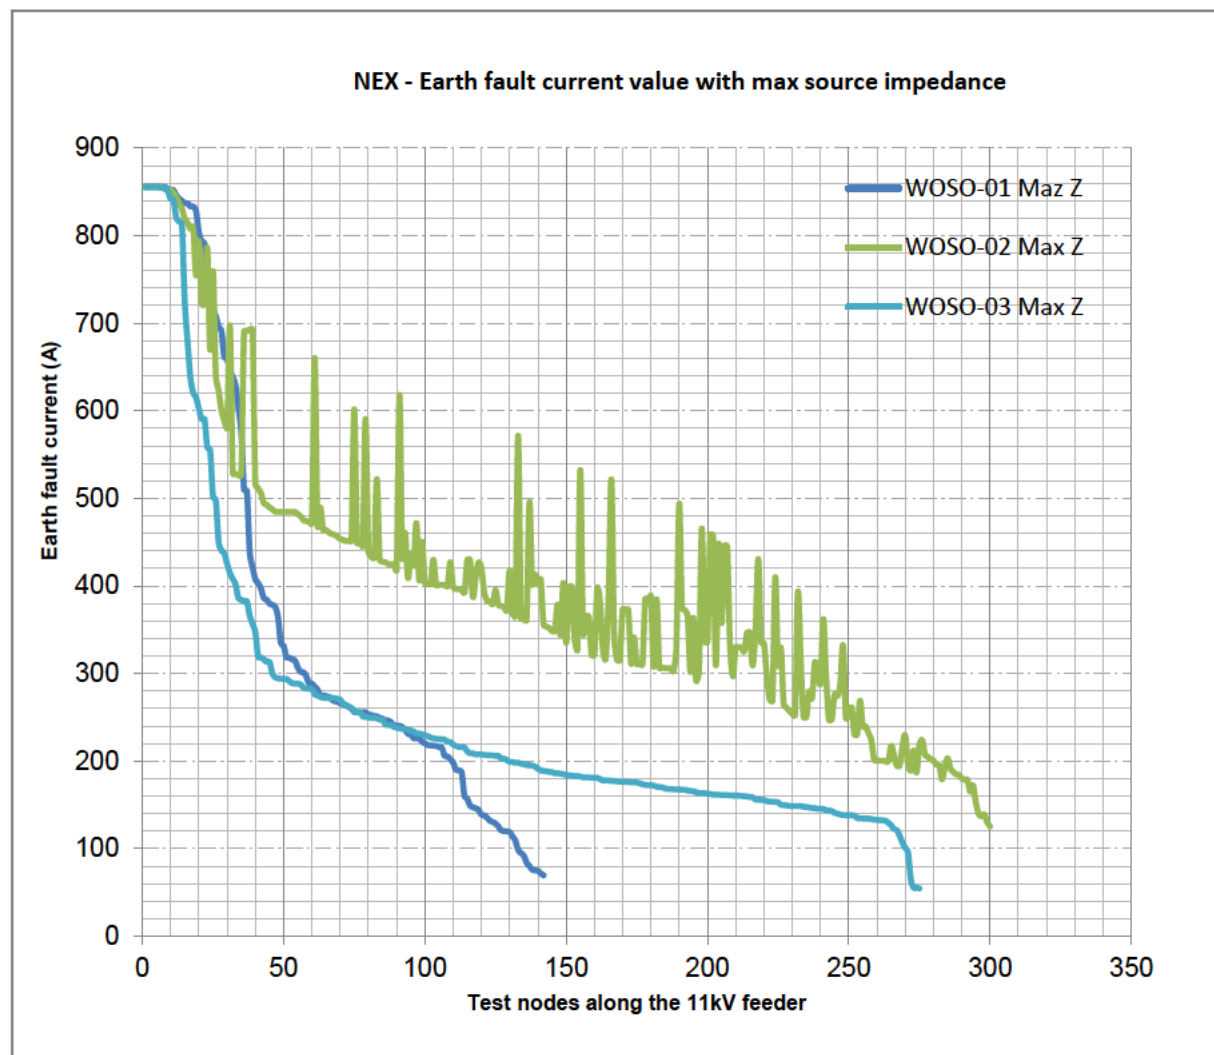

Figure 29: Solidly earth with min source impedance plus 50ohm fault resistance

Figure 30 below represents the result of analysis for an impedance earth system with maximum source impedance and no fault resistance in the network. A  $6\Omega$  Neutral Earthing Reactor (NEX) was added in the simulation to compare the earth fault current values with a solidly earth system. From the results it can be seen that maximum value of 855A earth fault current for each of the three feeders is at the substation in comparison to solidly earth system which had a value of 3212A at the same node. The minimum value of fault current recorded for WOSO-01 11kV feeder was 70A in comparison to WOSO-02 feeder which was 125A and WOSO-03 feeder was 55A. It was noted there was no change in minimum earth fault values between impedance earth system and solidly grounded system. It was also noted that WOSO-02 feeder had quite a bit of variation in magnitude of earth fault current.

*Figure 30: NEX earthing with max source impedance and no fault resistance*

Figure 31 below represents the result of analysis for impedance (NEX) earth system with minimum source impedance and no fault resistance in the network. From the results it can be seen that maximum value of earth fault current was 704A for each of the three feeders at the substation in comparison to figure 30 which had fault current of 855A at the same node. The minimum value of fault current recorded for WOSO-01 11kV feeder in this case was 27A in comparison to WOSO-02 feeder which was 56A and WOSO-03 feeder was 23A. It was again noted there was no change in minimum earth fault values between impedance earth system and solidly grounded system even though there was a difference in source impedance.

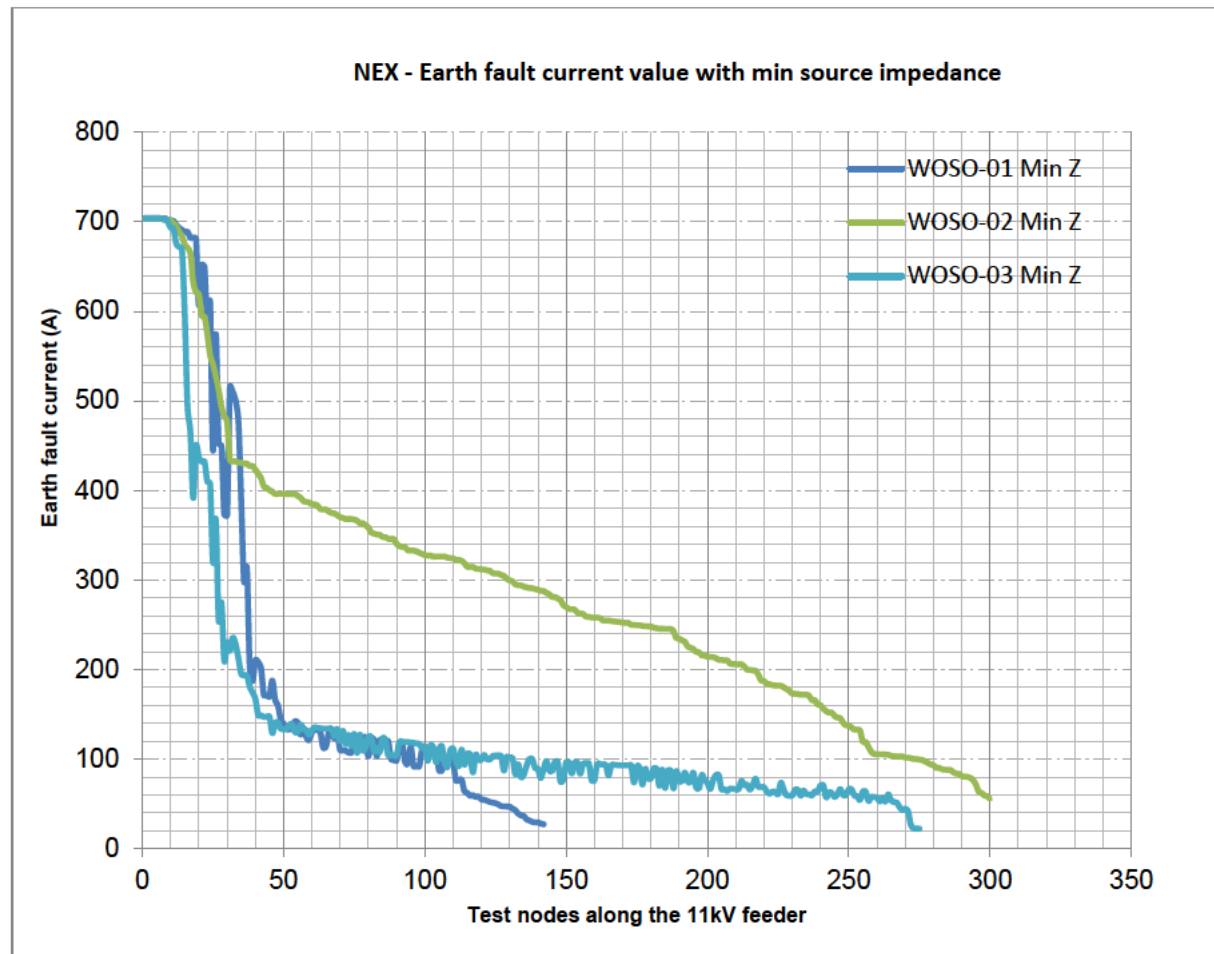

Figure 31: NEX earthing with min source impedance and no fault resistance

Figure 32 below represents the result of analysis for impedance earth system with maximum source impedance and 50Ω fault resistance in the network. From the results it can be seen that maximum value of earth fault current drops quite significantly to only 137A for each of the three feeders at the substation in comparison to figure 30 where the fault current at the same node was 855A. The minimum value of fault current recorded for WOSO-01 11kV feeder was 47A in comparison to WOSO-02 feeder which was 68A and WOSO-03 feeder was 40A. When comparing these minimum values of earth fault current to figure 30, it can be noted that there was a reduction of around 30% in earth fault current when fault resistance was introduced in the analysis.

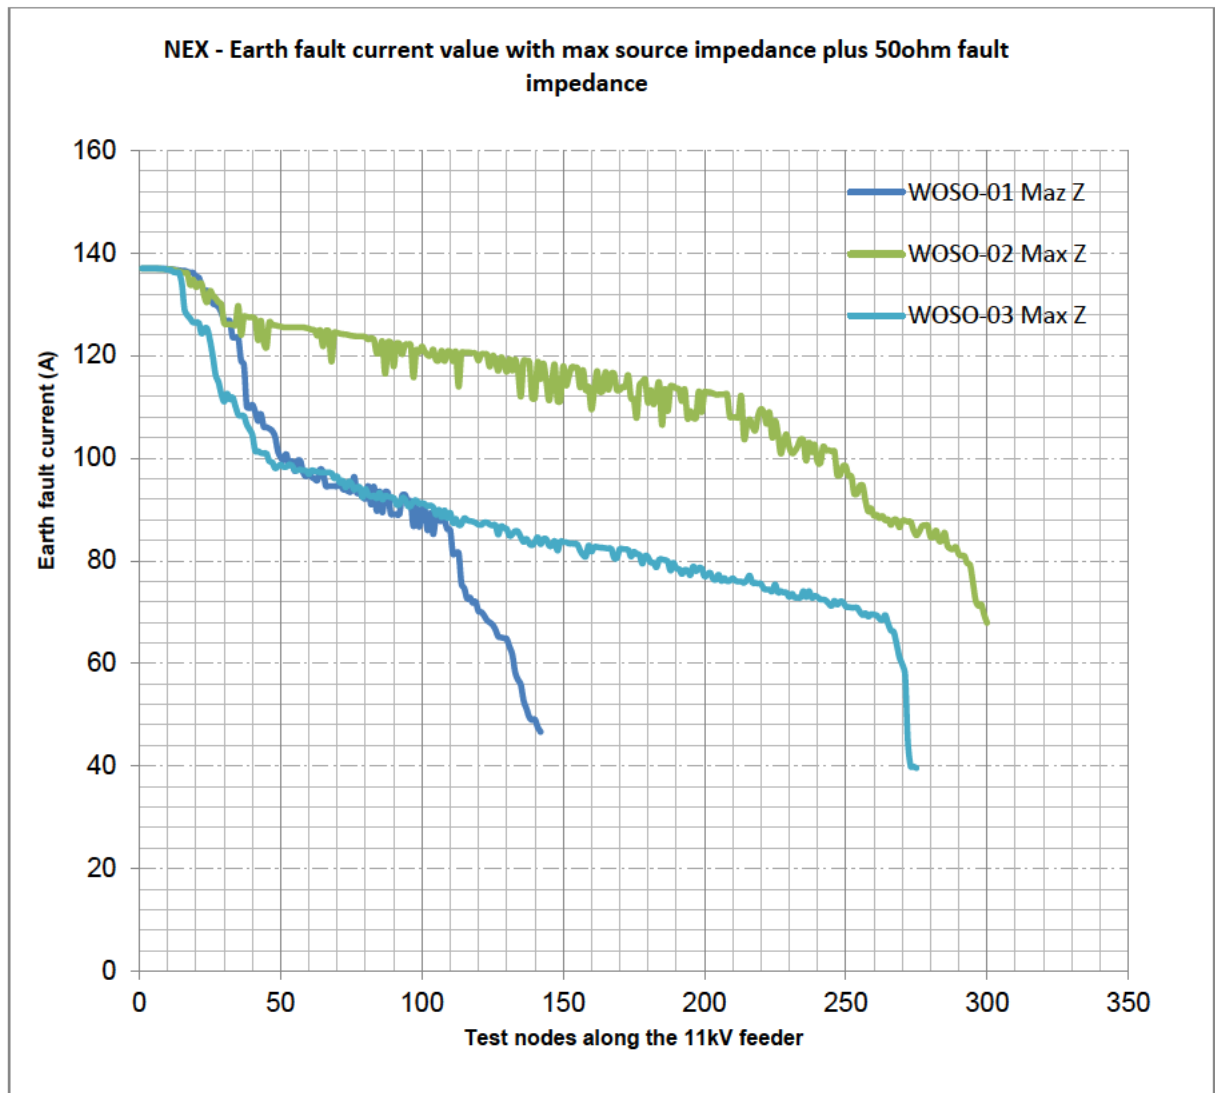

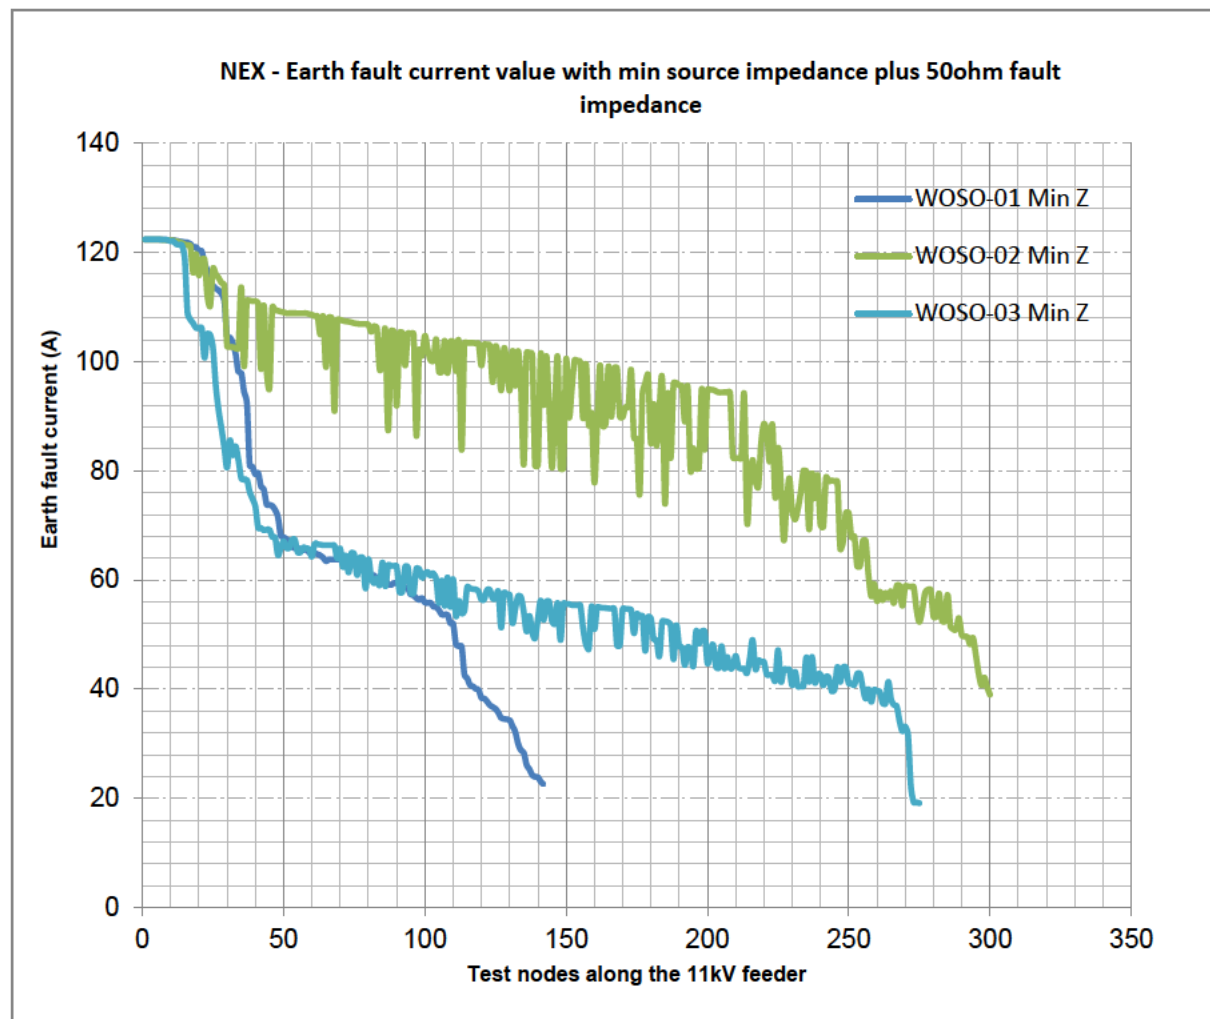

Figure 32: NEX earthing with max source impedance plus 50ohm fault resistance

Figure 33 below represents the result of analysis for impedance earth system with minimum source impedance and 50Ω fault resistance in the network. From the results it can be seen that maximum value of earth fault current drops quite significantly to only 122A for each of the three feeders at the substation in comparison to figure 31 where the fault current at the same node was 704A. The minimum value of fault current recorded for WOSO-01 11kV feeder was 23A in comparison to WOSO-02 feeder which was 39A and WOSO-03 feeder was 19A. When comparing these minimum values of earth fault current to figure 31, it can be noted that there was a only a small reduction of few Amps in earth fault current when fault resistance was introduced in the analysis.

*Figure 33: NEX earthing with min source impedance plus 50ohm fault resistance*

### 6.3 Fault detection times

For each of the 11kV feeders out of WOSO-01 substation an analysis was then carried out to check the fault detection times by primary protection device for minimum faults. The minimum faults did not include those spurs which were protected by master drop out fuse. The fault clearing time will then be represented by:

$$I_{f(t)} = \text{Fault Detection} + \text{Relay Operation} + \text{CB Operating}(\text{times})$$

#### 6.3.1 WOSO-01

The primary protection device for faults along WOSO-01 feeder is a digital protection relay at WOSO substation. The following table 12 highlights the fault detection times by the protection relay for fault current at site TVS2455 in each of the simulated scenarios. The site TVS2455 had the minimum value of fault current which needs to be detected by the protection relay at the substation.

<i>Simulated Scenarios</i>	<i>Fault Level (A)</i>	<i>Detection Time(s)</i>
Solidly Earth + Max Source Impedance	215	1.08
Solidly Earth + Min Source Impedance	98	3.34
Solidly Earth + Max Source Impedance + 50ohm Rf	86	4.25
Solidly Earth + Min Source Impedance + 50ohm Rf	56	13.36
6ohm NEX + Max Source Impedance	198	1.20
6ohm NEX + Min Source Impedance	95	3.53
6ohm NEX + Max Source Impedance + 50ohm Rf	85	4.25
6ohm NEX + Min Source Impedance + 50ohm Rf	55	13.36
3ohm NER + Max Source Impedance	198	1.20
3ohm NER + Min Source Impedance	93	3.53
3ohm NER + Max Source Impedance + 50ohm Rf	83	4.25
3ohm NER + Min Source Impedance + 50ohm Rf	54	13.36

Table 12: WOSO-01 Fault Detection Times for Minimum Fault

#### 6.3.2 WOSO-02

WOSO-02 feeder has a downstream Pole Mounted Recloser (PMR), therefore the PMR provides primary protection for faults beyond this PMR. The protection relay at WOSO substation provides primary protection for faults between the substation and the PMR. The following table 13 highlights the fault detection times by the protection relay for minimum fault current at site TVS37 in each of the simulated scenarios.

<i>Simulated Scenarios</i>	<i>Fault Level (A)</i>	<i>Detection Time(s)</i>
Solidly Earth + Max Source Impedance	592	0.67
Solidly Earth + Min Source Impedance	444	0.92
Solidly Earth + Max Source Impedance + 50ohm Rf	124	4.49
Solidly Earth + Min Source Impedance + 50ohm Rf	106	5.76
6ohm NEX + Max Source Impedance	402	1.02
6ohm NEX + Min Source Impedance	327	1.29
6ohm NEX + Max Source Impedance + 50ohm Rf	121	4.67
6ohm NEX + Min Source Impedance + 50ohm Rf	104	5.94

Table 13: WOSO-02 P142 Fault Detection Times for Minimum Fault

The following table 14 highlights the fault detection times by the Noja RC10 PMR for minimum fault current at site TVS3700 in each of the simulated scenarios. The site TVS3700 had the minimum value of fault current which needs to be detected by the PMR.

<i>Simulated Scenarios</i>	<i>Fault Level (A)</i>	<i>Detection Time(s)</i>
Solidly Earth + Max Source Impedance	183	0.22
Solidly Earth + Min Source Impedance	78	1.39
Solidly Earth + Max Source Impedance + 50ohm Rf	80	1.30
Solidly Earth + Min Source Impedance + 50ohm Rf	49	4.79

6ohm NEX + Min Source Impedance + 50ohm Rf	48	5.12

*Table 14: WOSO-02 Noja RC10 Fault Detection Times for Minimum Fault*

### 6.3.2 WOSO-03

WOSO-03 feeder also has a downstream PMR, therefore the PMR provides primary protection for faults beyond this PMR. The digital protection relay at WOSO substation provides primary protection for faults between the substation and the PMR. The following table 15 highlights the fault detection times by the protection relay for minimum fault current at site TVS2346 in each of the simulated scenarios.

<i>Simulated Scenarios</i>	<i>Fault Level (A)</i>	<i>Detection Time(s)</i>
Solidly Earth + Max Source Impedance	315	1.14
Solidly Earth + Min Source Impedance	140	3.18
Solidly Earth + Max Source Impedance + 50ohm Rf	99	5.47
Solidly Earth + Min Source Impedance + 50ohm Rf	67	12.47
6ohm NEX + Max Source Impedance	275	1.34
6ohm NEX + Min Source Impedance	135	3.35
6ohm NEX + Max Source Impedance + 50ohm Rf	98	5.57
6ohm NEX + Min Source Impedance + 50ohm Rf	67	12.47

*Table 15: WOSO-03 P142 Fault Detection Times for Minimum Fault*

The following table 16 highlights the fault detection times by the Noja RC10 PMR for minimum fault current at site TVS73 in each of the simulated scenarios.

<i>Simulated Scenarios</i>	<i>Fault Level (A)</i>	<i>Detection Time(s)</i>
Solidly Earth + Max Source Impedance	136	2.04
Solidly Earth + Min Source Impedance	61	12.76
Solidly Earth + Max Source Impedance + 50ohm Rf	70	7.0
Solidly Earth + Min Source Impedance + 50ohm Rf	42	42
6ohm NEX + Max Source Impedance	130	2.25
6ohm NEX + Min Source Impedance	60	13.33
6ohm NEX + Max Source Impedance + 50ohm Rf	69	9.32
6ohm NEX + Min Source Impedance + 50ohm Rf	41	46

*Table 16: WOSO-03 Noja RC10 Fault Detection Times for Minimum Fault*

The observations made from the fault detection times of minimum faults, was a significant delay in detection after fault resistance is introduced in the circuit. As the fault current drops, the detection times increases with respect to the protection settings implemented in the protection relay and corresponding fault current. With SEF protection implemented in all feeders, this will keep pick up to 7A and detection time to a maximum of 7s for lower values of fault current. Figure 34 below represents the detection times of minimum fault level in WOSO-01 feeder in various simulated scenarios. When compared to the other two feeders (WOSO-02 & WOSO-03) the behaviour of fault current and detection times is similar in each of the simulated scenarios.

*Figure 34: Graphical representation of WOSO-01 detection times*

The protection settings were not adjusted to improve detection times between the scenarios. Existing protection settings were utilised in each of the cases. The detection times can be improved by varying the pick-up current, time multiplier settings and curve selection. This will require checking the sizes of downstream fuses and designing the best possible protection settings for each of the scenarios.

## 6.4 High impedance earth fault

The following section demonstrates the characteristics of an actual high impedance earth fault and the effects it has on distribution power network. A high impedance earth fault occurred in the field past PMR as represented and shown in figure 35 below. It occurred on 11kV overhead feeder after 11kV pin insulator failed causing 11kV mains to sag down and rest on a fence.

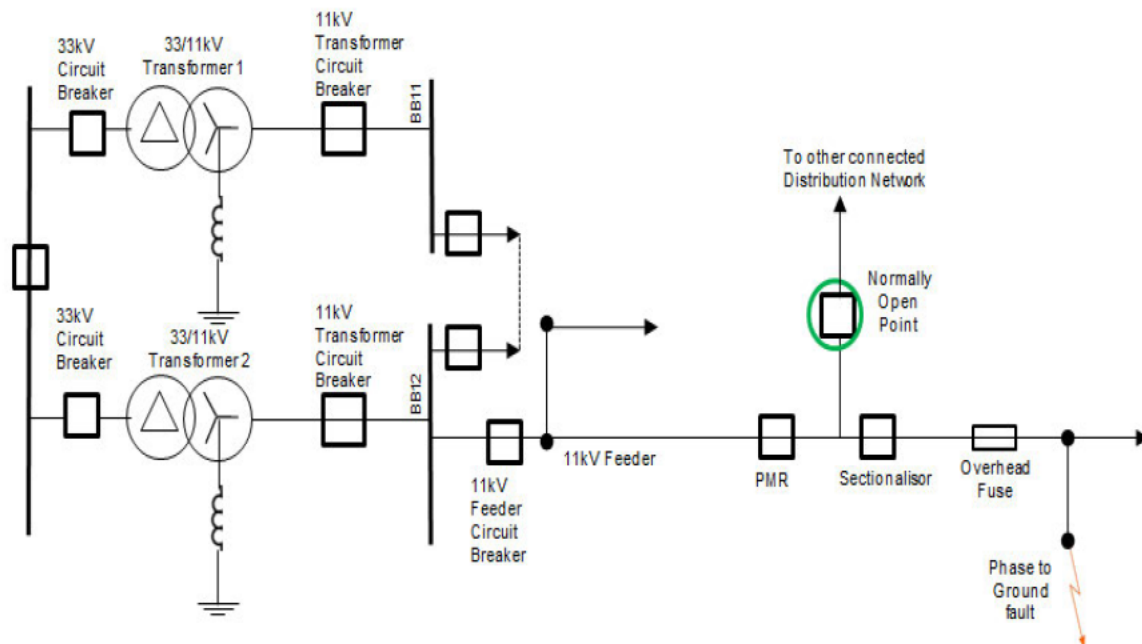

Figure 35: System Normal Configuration

Investigation of the protection devices on the faulted 11kV feeder was undertaken. It was determined that fault current was in the range of 0 – 10A and continuously fluctuated. The SEF protection on PMR would reset within its set fault reset time of 1s whenever the fault current dropped below the SEF pickup threshold of 5A. The feeder protection relay at the substation had fault reset time for the SEF element set at 2s and this was sufficient to allow the relay to operate for this fault (whilst the 1s reset time of the upstream PMR was not sufficient).

Phase to ground fault analysis at the fault location was undertaken in DINIS fault modelling software and the results are depicted in table 17 below:

Scenario	Fault Value
Phase to ground with no fault resistance	215A
Phase to ground fault with 50Ω fault resistance	85A
Phase to ground fault with 1000Ω fault resistance	6A

Table 17: Phase to ground simulation at fault location

Based on the fault analysis at the fault location, the fault resistance would have been in excess of 1000Ω, resulting in a high impedance earth fault which subsequently led to low values of fault current.

The event logs from the PMR are displayed in table 18 below. It can be observed that the SEF element in critical parameters column was picking up correctly but the fault did not persist long enough (more than 5sec) for the element to time out and issue a trip.

Date	Time	Event Title	Start / End	Source of Event	Relevant Phase	Critical Parameters
10-August-2019	9:49:37	Pickup	Start	SEF+	N	Iop, A=4

Table 18: PMR Event Log

The waveforms outlined in figures 36 and 37 display the fault recorded by the digital protection relay at the substation. These are two captures of the same fault as the relay recorded twice, as the fault current was fluctuating and the protection relay was resetting. It can be observed from the two captures of the waveforms that the fault current in the earth element only reached a peak of 10A and was continuously fluctuating. It can also be observed from the earth element waveform that the fault current drops below the pickup threshold of the protective devices.

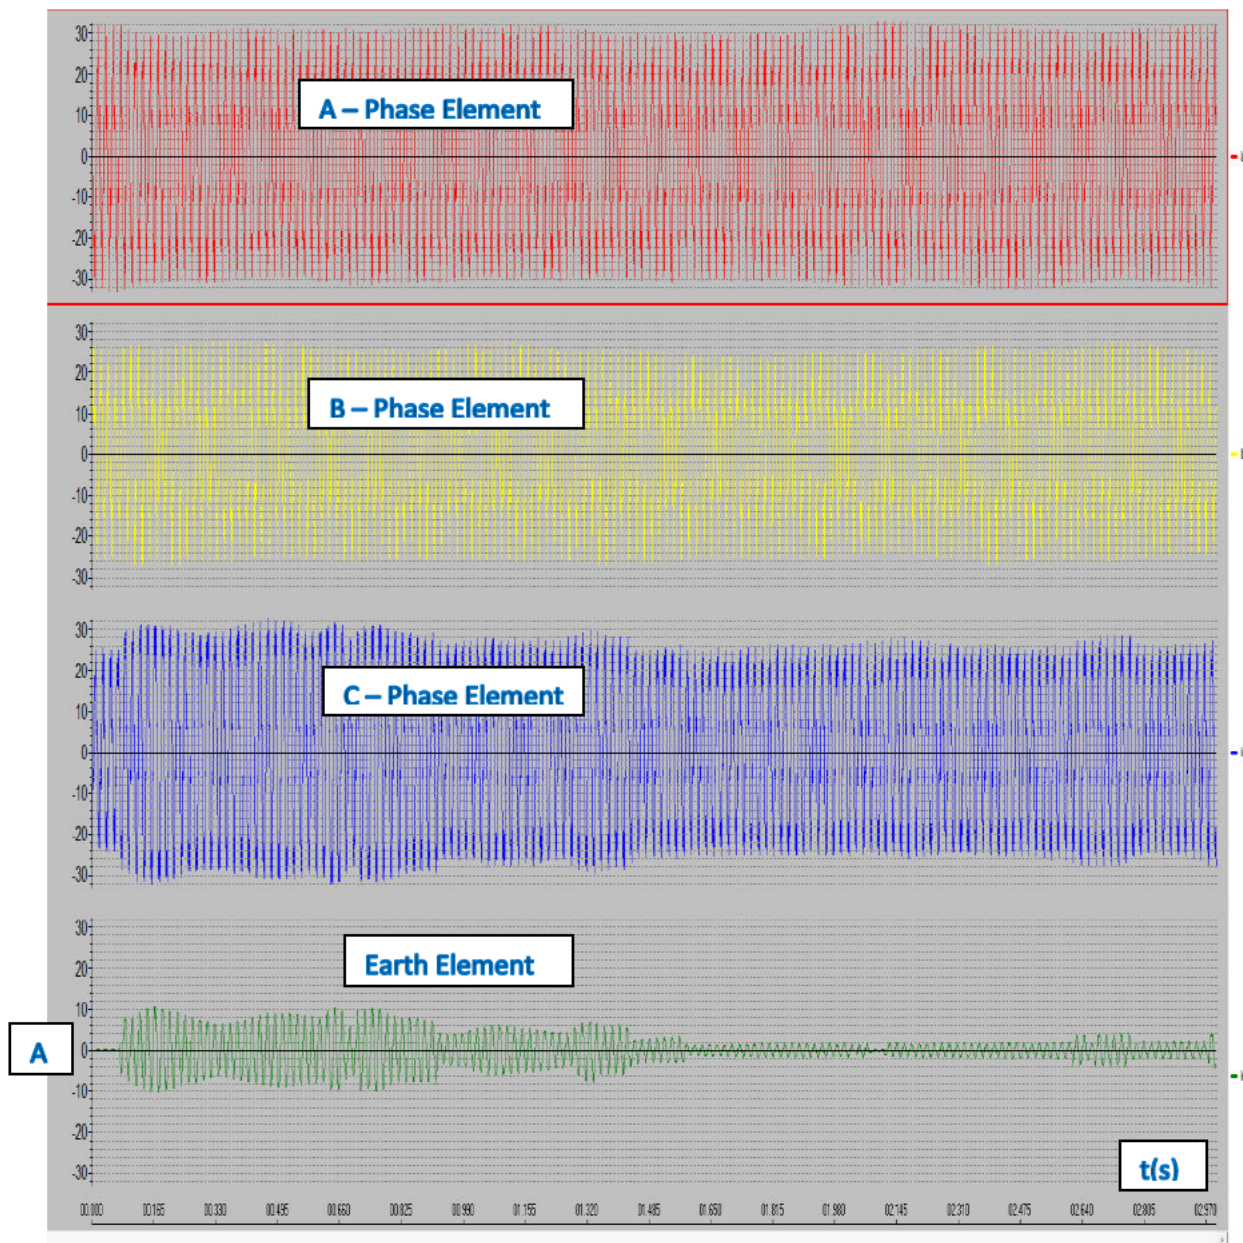

Figure 36: Substation 11kV Circuit Breaker Waveform 1

*Figure 37: Substation 11kV Circuit Breaker Waveform 2*

From this event it can be seen that, high impedance earth faults are bound to happen in the distribution power network. It is not a common fault that occurs in the network always but it can occur and have difficulties in being adequately detected. The fault current generated in this event was enough for Sensitive Earth Fault protection to detect and isolate the fault. In circumstances where the fault resistance is higher (greater than  $1000\Omega$ ), the fault current would have been lower which would then lead to detection issues by protection relays. This fault scenario highlights the need to have high impedance earth fault detection capable devices to be introduced in the network to improve safety and assist in the detection of all types of earth faults.

# Chapter 7 Proposed Earth Fault Detection

## 7.1 Chapter Overview

This chapter highlights the proposed earth fault detection technology which has been identified as part of this research project.

## 7.2 Rapid Earth Fault Current Limiter (REFCL)

REFCL's has been identified as a technology that can assist in improving safety and supply reliability in Energy Queensland's distribution power network. Literature suggests that where a bare line comes in contact with the ground or earthed object, (tree branch etc.), to avoid a fire starting the fault current needs to be limited to less than 500mA. Similarly, once a fault is detected, the circuit should not be re-energised to locate the fault with a current higher than 500mA. REFCL's offer the following benefits in comparison to existing protection devices:

- Response time of less than 60ms
- Reduces fault current to less than 500mA
- Detection capabilities of high impedance faults in the order of greater than 25kOhm
- Capabilities to reduce voltage on faulted conductor to 250V within 2s
- Reduced customer outages
- Fault location capabilities

REFCL's provides fast and complete compensation of all remaining earth fault currents – both fundamental and harmonics – by injecting a 180 degree opposite current into the neutral. In comparison to existing protective devices, REFCL's are able to reduce fault current to less than 500mA in under 3 cycles which traditional earth fault protection schemes and protective devices are not able to achieve. It is near impossible to set SEF pickup threshold down to 500mA due to feeder load and unbalanced network configurations. Accuracy of current transformers and protection relay pickup range also plays a key role in trying to achieve a pickup threshold of that low value.

The GFN employs resonant earthing with an additional residual current compensation feature which involves injecting current into an arc suppression coil at 180° out of phase with the residual fault current. The fundamental principle of resonant earthing is that in the event of a phase-to-earth fault, the tuned ASC creates a resonant circuit between the downstream network and neutral connection of the zone substation transformer resulting in a peak voltage displacement across the neutral. This leads to the faulted phase voltage becoming virtually zero, with the phase to ground voltages of the healthy phases increasing to almost phase to phase voltage in both 11kV and 22kV distribution network.

The neutral voltage displacement caused by this resonant circuit effectively leads to very low earth fault currents in comparison to non REFCL networks as the faulted phase voltage is too small to drive large currents. The power factor of the fault also approaches unity reducing arc flash risk, hence the name Arc Suppression Coil. The elevated phase to ground voltages on the healthy phase requires all equipment to be rated to withstand the overvoltage and consequently reduce the risk of cross country faults.

## 7.3 Network Components

Installation of REFCL's will require a shift in how the network is designed, operated and maintained as the transition from a low impedance grounded network to high impedance grounded network. As such all components of the entire 11kV and 22kV distribution network will need to be examined accordingly to understand and determine the requirements of a REFCL enabled network.

### 7.3.1 REFCL

The GFN is a package of products, which consist of a tuneable Arc Suppression Coil (ASC), Residual Current Compensator (RCC) and a control system. The ASC is connected to the power transformer neutral and is located in the switchyard. ASC is oil filled (hermetically sealed) consequently requiring its own bund. The ASC's purpose is to compensate for the network's capacitive coupling current during an earth fault leaving only a low residual fault current. As such the size of the ASC is determined by the size of the network. In order to compensate for the network's capacitive coupling current the ASC must be tuned to the network. The tuneable ASC is of a fixed inductance and variable capacitance type with auxiliary windings. The auxiliary windings are used for the LV tuning capacitor banks located on top of the ASC and for the RCC. The LV tuning capacitors will have capacitor banks that can be configured to offset the inductance of the ASC in order to tune the coil to the network capacitance. This adjustment enables the ASC to fully compensate for all scenarios, where feeders or sections in the network have been switched in or out. A tuning limitation will be set dictating the size of the ASC per zone substation.

The RCC is an AC-DC-AC converter that is housed in the zone substation control building or switch room. Its purpose is to neutralize the remaining residual fault current. The size of the RCC inverter is determined by the size and characteristics of the network. Because the ASC compensates the capacitive coupling current, the RCC inverter can be designed with limited power to only compensate for the residual active current. The RCC inverter also needs to compensate for capacitive coupling current caused by any mismatch of the ASC. The control system of the GFN completes the protection and control functions tying all the components together. The panel houses the Master and Slave relays and also includes the Neutral Manager (HMI) which is used for operating the device. The GFN control system is then interfaced to the station via the interface controller.

### 7.3.3 Substation Auxiliary Supplies

The added station alternating current load will dramatically increase due to the RCC loading demand. Typically the RCC kVA will be 10-15% of the ASC kVA rating. As such, substations that have small station service transformers will need to be upgraded in order to supply the RCC load together with the station load. The 11kV/22kV insulation of the ring main unit supplying the station service transformers must also withstand the elevated phase to ground voltages due to REFCL operation.

### **7.3.4 Neutral Bus**

The introduction of the REFCL requires a neutral bus, enabling different earthing arrangements to be configured automatically. A neutral bus will be required on a per REFCL basis. One mode of the REFCL will automatically switch in the NER/NEX and will have a separate controller to manage the operation of each neutral bus circuit breaker. A solidly grounded earthing configuration can be achieved via the NER/NEX bypass circuit breaker or at the transformer neutral connection.

### **7.3.5 NER/NEX**

NER's and NEX's does not need to be made redundant by the installation of a REFCL, rather it can be modified to ensure the NER/NEX can be switched into service by the REFCL interface controller when required as designed by the use of neutral bus.

### **7.3.6 Surge Arrestors**

Due to the elevated phase to ground voltages during REFCL operation, 11kV and 22kV station and distribution feeder surge arrestors will need to be assessed and replaced accordingly.

### **7.3.7 11kV/22kV Cabling**

All 11kV/22kV underground cables used in the substations that have planned REFCL implementation will be required to withstand the overvoltage during REFCL operation. Any upgrades or installation of new cables are to be rated to ensure insulation levels are sufficient and the network capacitance seen by the REFCL is kept to a minimum.

### **7.3.8 11kV/22kV Switchgear**

Installation of new switchboards will vary from substation to substation depending on the insulation ratings of existing switchgear and the availability of accurate VT's and CT's to achieve compliance. An assessment will be required to be carried out on existing 11kV and 22kV switchgear in each of the nominated zone substations.

### **7.3.9 11kV/22kV Station VT's**

Due to the elevated phase to ground voltages during REFCL operation, VT's will need to be assessed and replaced accordingly. Each REFCL will also require a neutral voltage measurement for the transformer/bus it is connected to.

## 7.4 Cost Analysis of REFCL installation

Component	Cost	Comments
ASC + RCC + Control Cubicle	\$1,200,000	Cost of one set REFCL
Training + Commissioning	\$85,500	Around 15 days (\$5700 / day)
Developing EQL standards	Note 1	Cost of developing EQL standards
EQL's feasibility study, planning, design and site installation	Note 1	Detail feasibility study, planning, design and site installation cost's
Power system augmentation – new surge arrestors, regulators, switchboard upgrading etc.	Note 1	Cost incurred in carrying out augmentation works in the power system
On-going maintenance	Note 1	Cost in maintaining the equipment

\*Note 1 – Further detail cost will be worked out if REFCL's are to be utilised

*Table 19: REFCL cost analysis*

Table 19 highlights the brief outline of the cost in implementing REFCL's. It can be noted that the actual cost of equipment is quite expansive which only includes one set of REFCL. There will be further cost from suppliers (Swedish Neutral) to send their staff to train EQL staff and also to assist in commissioning phases. A detail cost analysis will be required to be done as part of further work's once it is decided by EQL that REFCL's is a device that can be implemented in the distribution network to assist in improving safety of network. This will include performing a detailed feasibility study, developing EQL REFCL standards to be incorporated with existing protection schemes, planning, designing and future maintenance / replacement cost.

## 7.5 Other detection techniques

### 7.5.1 VS-SEF logic

As part of literature review, Voltage Supervised Sensitive Earth Fault has also been identified as a logic that may assist in detection of high impedance earth faults. However this logic will require rigorous testing within EQL's network to confirm its suitability. It does however require voltage inputs and not all of EQL's field protective devices have voltage transformers installed which can be a challenging factor. It further requires point of wave closing algorithm in the protective devices which will also need to be considered whilst looking into the usage of this new logic.

## 7.5.2 Relay Vendors

The following relay manufacturers were contacted as part of the research project to find out about the improvements they are making in the area of low earth fault detection:

- Schneider Electric
- ABB – ASEA Brown Boveri
- SEL – Schweitzer Engineering Laboratories

The relay manufacturers do not have an immediate solution that can primarily focus in low earth fault detection and are continually working around this area to have protective devices with improved detection capabilities. Whilst the protection relays have low setting range and fast processing internal timers for tripping, the CT ratio's available in primary plant is a factor that plays a part in setting the minimum current pick up of SEF protection.

EQL currently utilises Noja RC10 as a protective device in the field, which comprises of a standard OSM recloser tank and has a settings limit of 1A for SEF, but Noja power can also have special matched CT build of the OSM Recloser which allows a minimum pickup of 200mA. It does comprise of a tripping time in the range of 0 -120s with a resolution of 0.01s.

EQL can work with Noja Power to have a special matched CT tank with RC10 controller, combined with Noja's proprietary protection algorithms in the RC10 to have SEF set at 500mA on required feeders. This however does require good feeder balancing, which EQL needs to work on in-order to achieve a real low value of SEF pick up current.

# Chapter 8 Conclusions and Further Work

## 8.1 Chapter Overview

This chapter outlines the conclusions, and further work which has been identified that is associated with the research project.

## 8.2 Conclusions

The primary objectives of this research project were to:

- Investigate the different earthing system's used in Energy Queensland's distribution network.
- Investigate the benefits and challenges of existing and alternate earthing systems.
- Investigate the various forms of earth fault protection currently used by distribution network service providers within Australia.
- Develop suitable distribution network models for the analysis of different earthing systems.
- Research and investigate alternate protection functions currently available in protective devices from suppliers / manufactures which can be utilised for detecting earth faults.
- Research and investigate the availability of new technologies that may provide better earth fault detection capabilities.

These objectives have been successfully accomplished and an earth fault detection method has been identified that can be utilised in Energy Queensland's distribution power network. REFCL's is a device with features that can assist further in improving safety in the distribution power network.

EQL can continue to utilise solidly and impedance / resistance neutral grounding methods as it does have advantages as highlighted in the research. Other power utilities in Australia are also investigating methods and cost benefit solutions that can further assist in low earth fault current detection. Protection relay manufacturers are also actively doing research and working with power utilities to explore opportunities to improve their product so that it is continually able to meet the requirements of adequately protected power network.

It is intended that any of the detection methods highlighted as part of this project shall be subjected to further testing to confirm its suitability and viability to EQL's distribution power network.

## 8.3 Further Work

The following further work has been identified as part of the research project that can be undertaken to further improve earth fault detection in EQL's distribution power network:

- Detail feasibility and cost analysis of implementing Rapid Earth Fault Current Limiter technology.
- Further laboratory and field testing of Voltage Supervised – Sensitive Earth Fault logic to confirm its suitability in distribution power network.
- Power utilities to work in-conjunction with protection relay manufacturers to keep developing algorithms which are built in protection relays which can further assist in low values of earth fault detection.

# Appendix A – Project Specification

ENG4111/4112 Research Project

## Project Specification

For: Sanjay Narayan

Title: Analysis of Different Earthing Systems and Earth Fault Protection in Power System Distribution Network.

Major: Power Engineering

Supervisors: Andrew Hewitt\*, Matthew Quinton

Sponsorship: Energy Queensland Pty Limited

Enrolment: ENG4111 – Ext S1, 2019

ENG4112 – Ext S2, 2019

Project Aim: To investigate the effects of different earthing systems on the operation and effectiveness of earth fault protection schemes, with a focus on the Energy Queensland's distribution network.

**Programme: Version 3, 15<sup>th</sup> March 2018**

1. Investigate the different earthing system's used in Energy Queensland's distribution network.
2. Investigate the benefits and challenges of existing and alternate earthing systems.
3. Investigate the various forms of earth fault protection currently used by distribution network service providers within Australia.
4. Develop suitable distribution network models for the analysis of different earthing systems.
5. Research and investigate alternate protection functions currently available in protective devices from suppliers / manufactures which can be utilised for detecting earth faults.
6. Research and investigate the availability of new technologies that may provide better earth fault detection capabilities.

*If time and resources permit:*

7. Obtain measured fault data from the field to assess and validate assumptions and/or predictions made.
8. Study and analyse the effects of fault current on substation earth grid.

## Appendix B – Risk Assessment

A risk assessment was conducted to minimise risk to allow successful completion of this project. All identified risks was categorised according to:

- Risks to the safety of persons involved in the research project
- Risks to the completion of the research project
- Risks following the completion of the research project

Various control measures have been identified to eliminate the risk where it was possible to do so, or minimise the exposure to the risk where the risk was of significant danger to the work being conducted. The severity of the risks has been categorised as per Table 20 which has been extracted from Energex's risk management document M888.

Health & Safety Risks				
Risk Score	Risk Descriptor	Risk Tolerability Criteria and Action Requirements		
30 - 36	Extreme Risk	<b>Intolerable</b> (stop exposure immediately)		
24 - 29	Very High Risk	Risk must be managed in line with the ALARP Principles	Executive/Safety Council Approval (required to continue risk exposure)	May need full QRA Establish & implement appropriate mix of hard and soft controls according to the Hierarchy of Risk Controls and Cost-Benefit Analysis. Review their effectiveness.
18 - 23	High Risk		Divisional Manager/General Manager Approval (required to continue risk exposure)	Establish & implement appropriate mix of hard and soft controls according to the Hierarchy of Risk Controls and Cost-Benefit Analysis. Review their effectiveness.
11 - 17	Medium Risk		Group Manager/Process Owner Approval (required to continue risk exposure)	Review existing controls for effectiveness Introduce new or changed risk controls if cost-benefit justifiable
6 - 10	Low Risk		Line Manager/Field Distribution Manager (or equivalent) Approval (required to continue risk exposure)	Continual Review of existing controls for effectiveness Introduce new or changed risk controls if cost-benefit justifiable
1 - 5	Very Low Risk		Supervisor/Coordinator Approval (or equivalent) (required to continue risk exposure)	Continual Review of existing controls for effectiveness

Table 20: Risk Tolerability Scale

Table 21 specifies the hierarchy of controls that was used to mitigate the hazards. The most preferred option of hazard management was applied first.

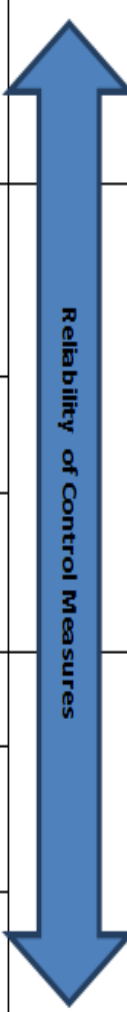

Risk Treatment / Control Hierarchy					
HARD Options - Most preferred – Consider First ( less dependent on human reliability - can appear to be more costly )					
	Level	Control Hierarchy		Risk Treatment	
 Highest	1	Elimination / Substitution	Physical / Engineering	eliminating / removing exposure to the hazardous object, material, substance, method or procedure , or replacing it with another that has a lower risk for the same exposure <i>For example, not using an EWP that has been identified as having faulty controls or using a chemical with a lower toxicity or flammability but still achieves the same function or outcome.</i>	 Most
				better initial design / ergonomics and reengineering / redesign which introduces new methods of physical operation, barriers , safe-guards or safety devices to reduce the risk exposure <i>For example, design an overhead network to enable de-energised work or ergonomic redesign of tools and equipment</i>	
	2	Design		distance or time separation of hazards and exposed persons <i>For example, demarcation / barricading exclusion zones for fall / drop hazards</i>	
		Separation		improved or new rules / procedures / scheduling / maintenance / communications – better involvement of users in risk assessments / review or development of better user documents, signage, messages, notices	
	3	Administration		selection and preparation of personnel / behaviour reinforcement methods / fair and just culture discipline /culture	
		Supervisor / Enforcement		Audits / Inspections / reviews / risk assessments / frequency / depth <i>For example, scheduling work on / near roadways outside of peak hours or improved checking on actual operations and activities. Better / different frequency maintenance inspections / servicing</i>	
		Checking / Assessments		wearing PPE Personal protective equipment - providing protective clothing or equipment to exposed personnel – Training – all kinds, - Behaviour observation / interaction related programs. <i>For example, better Initial and refresher training for high risk activities.</i>	
Least		Behaviour-Related Measures			Lowest
SOFT Options - Least preferred (– more dependent on human reliability - can appear to be less costly )					
Notes					
1) Always use multiple controls – never rely on only 1 - the more controls the less likely that all will fail / be ineffective at the same time 2) Always use a combination of controls from different parts of hierarchy – even HARD controls at the top of the hierarchy are not perfect 3) Always use pre-emptive controls which reduce Likelihood L as well as reactive responsive controls which primarily reduce Consequence C 4) Always consider effectiveness of control options – not just cost 5) “Better Ergonomics” means changing design and methods of use to better match human operators’ capabilities and limitations					

Table 21: Hierarchy of Hazard Control

Table 22 below identified the personnel hazards which were expected at various stages of the research project and appropriate control measures that was implemented to prevent any injuries and risk.

Hazard	Risk	Control Measures and Mitigation
<b>Office Environment Hazard</b>		
<ul style="list-style-type: none"> <li>Ergonomic Hazards</li> </ul>	Minor / Possible (Low Risk)	<ul style="list-style-type: none"> <li>Take regular breaks</li> <li>Maintain proper sitting posture</li> <li>Computer screen, keyboard, mouse are correctly located</li> <li>Desk and Chair are correctly adjusted</li> </ul>
<ul style="list-style-type: none"> <li>Poor or inadequate lighting</li> </ul>	Minor / Possible (Very Low Risk)	<ul style="list-style-type: none"> <li>Turn on all lights in the area</li> </ul>
<ul style="list-style-type: none"> <li>Electrical hazards such as power leads</li> </ul>	Minor / Possible (Very Low Risk)	<ul style="list-style-type: none"> <li>Cords and leads are neatly placed and clear off work areas</li> </ul>
<b>Field Environment Hazards</b>		
<ul style="list-style-type: none"> <li>Manual Handling</li> </ul>	Minor / Possible (Medium Risk)	<ul style="list-style-type: none"> <li>Site specific risk assessment</li> <li>Strictly follow lifting weight limitations</li> <li>Use two men lift where required</li> <li>Follow good lifting techniques</li> <li>Use mechanical or other forms of aid where available</li> </ul>
<ul style="list-style-type: none"> <li>Slip Trips and Falls</li> </ul>	Minor / Possible (Medium Risk)	<ul style="list-style-type: none"> <li>Site specific risk assessment</li> <li>Beware of surroundings</li> <li>Keep all equipment / leads etc away from work area</li> <li>Watch step while moving around</li> </ul>
<ul style="list-style-type: none"> <li>Extreme temperatures</li> </ul>	Minor / Possible (Medium Risk)	<ul style="list-style-type: none"> <li>Site specific risk assessment</li> <li>Plenty drinking water is available</li> <li>Use sun protection (Hard hats with brim, long sleeve shirt / trousers, sunscreen lotion, sunglasses)</li> </ul>
<ul style="list-style-type: none"> <li>Electric shock</li> </ul>	Minor / Possible (Medium Risk)	<ul style="list-style-type: none"> <li>Site specific risk assessment</li> <li>Isolate plant where necessary</li> <li>Apply for permits and network access</li> <li>Clearly define and delineate work area</li> <li>Place work area signs</li> </ul>
<ul style="list-style-type: none"> <li>Height</li> </ul>	Minor / Possible (Medium Risk)	<ul style="list-style-type: none"> <li>Site specific risk assessment</li> <li>Use men lifting trucks where possible</li> <li>Ladders are well secured</li> <li>Harnesses are correctly used</li> </ul>

*Table 22: Personal Risk Assessment*

Table 23 below identified the risk to the actual research project which can potentially lead into unsuccessful completion of the study if it was not controlled or mitigated.

Hazard	Risk	Control Measures and Mitigation
<ul style="list-style-type: none"> <li>Failure of systems such as PC's and laptops</li> </ul>	Minor / Possible (Low Risk)	<ul style="list-style-type: none"> <li>Always have backup copies of all working documents and models</li> </ul>
<ul style="list-style-type: none"> <li>Access restrictions to data base and systems</li> </ul>	Minor / Unlikely (Very Low Risk)	<ul style="list-style-type: none"> <li>Request access in advance</li> <li>Seek assistance from personnel who already have access to systems</li> </ul>
<ul style="list-style-type: none"> <li>Delay in response time from suppliers / manufacturers</li> </ul>	Minor / Unlikely (Very Low Risk)	<ul style="list-style-type: none"> <li>Request for information in advance</li> <li>Always follow up on correspondence</li> </ul>

*Table 23: Project Risk Assessment*

Table 24 below identified the risk to the research project upon reaching completion.

Hazard	Risk	Control Measures and Mitigation
<ul style="list-style-type: none"> <li>Implementation of alternate earthing systems and alternate detection methods</li> </ul>	Minor / Possible (Low Risk)	<ul style="list-style-type: none"> <li>Further studies could be required by other departments</li> <li>Cost analysis for a roll out program</li> </ul>

*Table 24: Post Project Risk Assessment*

## Appendix C – Operating Schematic of WOSO

The image displays the DigSILENT PowerFactory software interface. The top window shows a single-line diagram of a power system with a transformer and various busbars. The bottom window displays the '2-Winding Transformer - WOSO\TVS1009 PO2143535\TVS1009/110790.T1.ElmTr2' configuration dialog. The 'General' tab is active, showing fields for Name, Type, HV-Side, LV-Side, Zone, Area, and Out of Service status. The 'Supplied Elements' section includes buttons for 'Mark Elements in Graphic' and 'Edit Elements'. The bottom status bar shows a schematic diagram of the transformer with HV and LV sides.

## Appendix E – Results of Earthing Systems

The following table displays measured earth fault current on A-phase in WOSO-01 11kV feeder with different earthing systems:

Maximum Source Impedance and No Fault Resistance			
Test Nodes	Solidly Earth(A)	6 $\Omega$ NEX(A)	3 $\Omega$ NER(A)

The following results shows measured earth fault current on A-phase in WOSO-02 11kV feeder with different earthing systems, varying source impedance and also adding 50Ω fault resistance:

Test Nodes	Solidly Earth				Neutral Earthing Reactor (NEX)			
	Max Z(A)	Min Z(A)	Max Z & 50Ω Rf(A)	Min Z & 50Ω Rf(A)	Max Z(A)	Min Z(A)	Max Z & 50Ω Rf(A)	Min Z & 50Ω Rf(A)

The following results shows measured earth fault current on A-phase in WOSO-03 11kV feeder with different earthing systems, varying source impedance and also adding 50Ω fault resistance:

Test Nodes	Solidly Earth				Neutral Earthing Reactor (NEX)			
	Max Z(A)	Min Z(A)	Max Z & 50Ω Rf(A)	Min Z & 50Ω Rf(A)	Max Z(A)	Min Z(A)	Max Z & 50Ω Rf(A)	Min Z & 50Ω Rf(A)
